array([222222.+111111.j, 111111.          +0.j, 111111.+222222.j])
>>> nan = np.array([11, 12, 13])
>>> posinf = np.array([21, 22, 23])
>>> neginf = np.array([31, 32, 33])
>>> np.nan_to_num(y, nan=nan, posinf=posinf, neginf=neginf)
array([21.+11.j, 12. +0.j, 13.+23.j])

```

`numpy.real_if_close(a, tol=100)`

If input is complex with all imaginary parts close to zero, return real parts.

“Close to zero” is defined as $tol * (\text{machine epsilon of the type for } a)$.

Parameters

a

[array_like] Input array.

tol

[float] Tolerance in machine epsilons for the complex part of the elements in the array. If the tolerance is ≤ 1 , then the absolute tolerance is used.

Returns

out

[ndarray] If *a* is real, the type of *a* is used for the output. If *a* has complex elements, the returned type is float.

See also:

[*real*](#), [*imag*](#), [*angle*](#)

Notes

Machine epsilon varies from machine to machine and between data types but Python floats on most platforms have a machine epsilon equal to $2.2204460492503131e-16$. You can use `'np.finfo(float).eps'` to print out the machine epsilon for floats.

Examples

```
>>> import numpy as np
>>> np.finfo(float).eps
2.2204460492503131e-16 # may vary
```

```
>>> np.real_if_close([2.1 + 4e-14j, 5.2 + 3e-15j], tol=1000)
array([2.1, 5.2])
>>> np.real_if_close([2.1 + 4e-13j, 5.2 + 3e-15j], tol=1000)
array([2.1+4.e-13j, 5.2 + 3e-15j])
```

`numpy.interp(x, xp, fp, left=None, right=None, period=None)`

One-dimensional linear interpolation for monotonically increasing sample points.

Returns the one-dimensional piecewise linear interpolant to a function with given discrete data points (*xp*, *fp*), evaluated at *x*.

Parameters

x

[array_like] The x-coordinates at which to evaluate the interpolated values.

xp

[1-D sequence of floats] The x-coordinates of the data points, must be increasing if argument *period* is not specified. Otherwise, *xp* is internally sorted after normalizing the periodic boundaries with `xp = xp % period`.

fp

[1-D sequence of float or complex] The y-coordinates of the data points, same length as *xp*.

left

[optional float or complex corresponding to fp] Value to return for $x < xp[0]$, default is *fp*[0].

right

[optional float or complex corresponding to fp] Value to return for $x > xp[-1]$, default is *fp*[-1].

period

[None or float, optional] A period for the x-coordinates. This parameter allows the proper interpolation of angular x-coordinates. Parameters *left* and *right* are ignored if *period* is specified.

Returns

y

[float or complex (corresponding to fp) or ndarray] The interpolated values, same shape as *x*.

Raises

ValueError

If *xp* and *fp* have different length If *xp* or *fp* are not 1-D sequences If *period* == 0

Warning: The x-coordinate sequence is expected to be increasing, but this is not explicitly enforced. However, if the sequence *xp* is non-increasing, interpolation results are meaningless.

Note that, since NaN is unsortable, *xp* also cannot contain NaNs.

A simple check for *xp* being strictly increasing is:

```
np.all(np.diff(xp) > 0)
```

See also:

`scipy.interpolate`

Examples

```
>>> import numpy as np
>>> xp = [1, 2, 3]
>>> fp = [3, 2, 0]
>>> np.interp(2.5, xp, fp)
1.0
>>> np.interp([0, 1, 1.5, 2.72, 3.14], xp, fp)
array([3. , 3. , 2.5 , 0.56, 0.  ])
>>> UNDEF = -99.0
>>> np.interp(3.14, xp, fp, right=UNDEF)
-99.0
```

Plot an interpolant to the sine function:

```
>>> x = np.linspace(0, 2*np.pi, 10)
>>> y = np.sin(x)
>>> xvals = np.linspace(0, 2*np.pi, 50)
>>> yinterp = np.interp(xvals, x, y)
>>> import matplotlib.pyplot as plt
>>> plt.plot(x, y, 'o')
[<matplotlib.lines.Line2D object at 0x...>]
>>> plt.plot(xvals, yinterp, '-x')
[<matplotlib.lines.Line2D object at 0x...>]
>>> plt.show()
```

Interpolation with periodic x-coordinates:

```
>>> x = [-180, -170, -185, 185, -10, -5, 0, 365]
>>> xp = [190, -190, 350, -350]
>>> fp = [5, 10, 3, 4]
```

(continues on next page)

(continued from previous page)

```
>>> np.interp(x, xp, fp, period=360)
array([7.5 , 5.   , 8.75, 6.25, 3.   , 3.25, 3.5 , 3.75])
```

Complex interpolation:

```
>>> x = [1.5, 4.0]
>>> xp = [2, 3, 5]
>>> fp = [1.0j, 0, 2+3j]
>>> np.interp(x, xp, fp)
array([0.+1.j , 1.+1.5j])
```

1.4.13 Miscellaneous routines

Performance tuning

<code>setbufsize(size)</code>	Set the size of the buffer used in ufuncs.
<code>getbufsize()</code>	Return the size of the buffer used in ufuncs.

`numpy.setbufsize(size)`

Set the size of the buffer used in ufuncs.

Changed in version 2.0: The scope of setting the buffer is tied to the `numpy.errstate` context. Exiting a `with errstate()` : will also restore the bufsize.

Parameters

size

[int] Size of buffer.

Returns

bufsize

[int] Previous size of ufunc buffer in bytes.

Notes

Concurrency note: see *Floating point error handling*

Examples

When exiting a `numpy.errstate` context manager the bufsize is restored:

```
>>> import numpy as np
>>> with np.errstate():
...     np.setbufsize(4096)
...     print(np.getbufsize())
...
8192
4096
>>> np.getbufsize()
8192
```

`numpy.getbufsize()`

Return the size of the buffer used in ufuncs.

Returns

getbufsize

[int] Size of ufunc buffer in bytes.

Notes

Concurrency note: see *Floating point error handling*

Examples

```
>>> import numpy as np
>>> np.getbufsize()
8192
```

Memory ranges

<code>shares_memory(a, b, /[, max_work])</code>	Determine if two arrays share memory.
<code>may_share_memory(a, b, /[, max_work])</code>	Determine if two arrays might share memory

`numpy.shares_memory(a, b, /, max_work=-1)`

Determine if two arrays share memory.

Warning: This function can be exponentially slow for some inputs, unless *max_work* is set to zero or a positive integer. If in doubt, use `numpy.may_share_memory` instead.

Parameters

a, b

[ndarray] Input arrays

max_work

[int, optional] Effort to spend on solving the overlap problem (maximum number of candidate solutions to consider). The following special values are recognized:

max_work=-1 (default)

The problem is solved exactly. In this case, the function returns True only if there is an element shared between the arrays. Finding the exact solution may take extremely long in some cases.

max_work=0

Only the memory bounds of a and b are checked. This is equivalent to using `may_share_memory()`.

Returns

out

[bool]

Raises

numpy.exceptions.TooHardError
Exceeded `max_work`.

See also:

[`may\_share\_memory`](#)

Examples

```
>>> import numpy as np
>>> x = np.array([1, 2, 3, 4])
>>> np.shares_memory(x, np.array([5, 6, 7]))
False
>>> np.shares_memory(x[::2], x)
True
>>> np.shares_memory(x[::2], x[1::2])
False
```

Checking whether two arrays share memory is NP-complete, and runtime may increase exponentially in the number of dimensions. Hence, `max_work` should generally be set to a finite number, as it is possible to construct examples that take extremely long to run:

```
>>> from numpy.lib.stride_tricks import as_strided
>>> x = np.zeros([192163377], dtype=np.int8)
>>> x1 = as_strided(
...     x, strides=(36674, 61119, 85569), shape=(1049, 1049, 1049))
>>> x2 = as_strided(
...     x[64023025:], strides=(12223, 12224, 1), shape=(1049, 1049, 1))
>>> np.shares_memory(x1, x2, max_work=1000)
Traceback (most recent call last):
...
numpy.exceptions.TooHardError: Exceeded max_work
```

Running `np.shares_memory(x1, x2)` without `max_work` set takes around 1 minute for this case. It is possible to find problems that take still significantly longer.

`numpy.may_share_memory(a, b, /, max_work=0)`

Determine if two arrays might share memory

A return of `True` does not necessarily mean that the two arrays share any element. It just means that they *might*.

Only the memory bounds of `a` and `b` are checked by default.

Parameters

a, b

[ndarray] Input arrays

max_work

[int, optional] Effort to spend on solving the overlap problem. See [`shares\_memory`](#) for details. Default for `may_share_memory` is to do a bounds check.

Returns

out

[bool]

See also:

shares_memory

Examples

```
>>> import numpy as np
>>> np.may_share_memory(np.array([1,2]), np.array([5,8,9]))
False
>>> x = np.zeros([3, 4])
>>> np.may_share_memory(x[:,0], x[:,1])
True
```

Utility

<code>get_include()</code>	Return the directory that contains the NumPy *.h header files.
<code>show_config([mode])</code>	Show libraries and system information on which NumPy was built and is being used
<code>show_runtime()</code>	Print information about various resources in the system including available intrinsic support and BLAS/LAPACK library in use
<code>broadcast_shapes(*args)</code>	Broadcast the input shapes into a single shape.

`numpy.get_include()`

Return the directory that contains the NumPy *.h header files.

Extension modules that need to compile against NumPy may need to use this function to locate the appropriate include directory.

Notes

When using `setuptools`, for example in `setup.py`:

```
import numpy as np
...
Extension('extension_name', ...
          include_dirs=[np.get_include()])
...
```

Note that a CLI tool `numpy-config` was introduced in NumPy 2.0, using that is likely preferred for build systems other than `setuptools`:

```
$ numpy-config --cflags
-I/path/to/site-packages/numpy/_core/include

# Or rely on pkg-config:
$ export PKG_CONFIG_PATH=$(numpy-config --pkgconfigdir)
$ pkg-config --cflags
-I/path/to/site-packages/numpy/_core/include
```

Examples

```
>>> np.get_include()
'.../site-packages/numpy/core/include' # may vary
```

`numpy.show_config(mode='stdout')`

Show libraries and system information on which NumPy was built and is being used

Parameters

mode

[{'stdout', 'dicts'}, optional.] Indicates how to display the config information. 'stdout' prints to console, 'dicts' returns a dictionary of the configuration.

Returns

out

[[dict, None]] If mode is 'dicts', a dict is returned, else None

See also:

[`get\_include`](#)

Returns the directory containing NumPy C header files.

Notes

1. The 'stdout' mode will give more readable output if `pyyaml` is installed

`numpy.show_runtime()`

Print information about various resources in the system including available intrinsic support and BLAS/LAPACK library in use

New in version 1.24.0.

See also:

[`show\_config`](#)

Show libraries in the system on which NumPy was built.

Notes

1. Information is derived with the help of `threadpoolctl` library if available.
2. SIMD related information is derived from `__cpu_features__`, `__cpu_baseline__` and `__cpu_dispatch__`

`numpy.broadcast_shapes(*args)`

Broadcast the input shapes into a single shape.

Learn more about broadcasting [here](#).

New in version 1.20.0.

Parameters

*args

[tuples of ints, or ints] The shapes to be broadcast against each other.

Returns**tuple**

Broadcasted shape.

Raises**ValueError**

If the shapes are not compatible and cannot be broadcast according to NumPy's broadcasting rules.

See also:

broadcast

broadcast_arrays

broadcast_to

Examples

```
>>> import numpy as np
>>> np.broadcast_shapes((1, 2), (3, 1), (3, 2))
(3, 2)
```

```
>>> np.broadcast_shapes((6, 7), (5, 6, 1), (7,), (5, 1, 7))
(5, 6, 7)
```

NumPy-specific help function

info([object, maxwidth, output, toplevel])

Get help information for an array, function, class, or module.

`numpy.info` (*object=None, maxwidth=76, output=None, toplevel='numpy'*)

Get help information for an array, function, class, or module.

Parameters**object**

[object or str, optional] Input object or name to get information about. If *object* is an *ndarray* instance, information about the array is printed. If *object* is a numpy object, its docstring is given. If it is a string, available modules are searched for matching objects. If None, information about *info* itself is returned.

maxwidth

[int, optional] Printing width.

output

[file like object, optional] File like object that the output is written to, default is None, in which case `sys.stdout` will be used. The object has to be opened in 'w' or 'a' mode.

toplevel

[str, optional] Start search at this level.

Notes

When used interactively with an object, `np.info(obj)` is equivalent to `help(obj)` on the Python prompt or `obj?` on the IPython prompt.

Examples

```
>>> np.info(np.polyval)
polyval(p, x)
    Evaluate the polynomial p at x.
...
```

When using a string for *object* it is possible to get multiple results.

```
>>> np.info('fft')
*** Found in numpy ***
Core FFT routines
...
*** Found in numpy.fft ***
fft(a, n=None, axis=-1)
...
*** Repeat reference found in numpy.fft.fftpack ***
*** Total of 3 references found. ***
```

When the argument is an array, information about the array is printed.

```
>>> a = np.array([[1 + 2j, 3, -4], [-5j, 6, 0]], dtype=np.complex64)
>>> np.info(a)
class: ndarray
shape: (2, 3)
strides: (24, 8)
itemsize: 8
aligned: True
contiguous: True
fortran: False
data pointer: 0x562b6e0d2860 # may vary
byteorder: little
byteswap: False
type: complex64
```

1.4.14 Polynomials

Polynomials in NumPy can be *created*, *manipulated*, and even *fitted* using the *convenience classes* of the `numpy.polynomial` package, introduced in NumPy 1.4.

Prior to NumPy 1.4, `numpy.poly1d` was the class of choice and it is still available in order to maintain backward compatibility. However, the newer `polynomial` package is more complete and its *convenience classes* provide a more consistent, better-behaved interface for working with polynomial expressions. Therefore `numpy.polynomial` is recommended for new coding.

Note: Terminology

The term *polynomial module* refers to the old API defined in `numpy.lib.polynomial`, which includes the `numpy.poly1d` class and the polynomial functions prefixed with *poly* accessible from the `numpy` namespace (e.g. `numpy.polyadd`, `numpy.polyval`, `numpy.polyfit`, etc.).

The term *polynomial package* refers to the new API defined in `numpy.polynomial`, which includes the convenience classes for the different kinds of polynomials (*Polynomial*, *Chebyshev*, etc.).

Transitioning from `numpy.poly1d` to `numpy.polynomial`

As noted above, the *poly1d* class and associated functions defined in `numpy.lib.polynomial`, such as `numpy.polyfit` and `numpy.poly`, are considered legacy and should **not** be used in new code. Since NumPy version 1.4, the `numpy.polynomial` package is preferred for working with polynomials.

Quick Reference

The following table highlights some of the main differences between the legacy polynomial module and the polynomial package for common tasks. The *Polynomial* class is imported for brevity:

```
from numpy.polynomial import Polynomial
```

How to...	Legacy (<i>numpy.poly1d</i>)	<i>numpy.polynomial</i>
Create a polynomial object from coefficients ¹	<code>p = np.poly1d([1, 2, 3])</code>	<code>p = Polynomial([3, 2, 1])</code>
Create a polynomial object from roots	<code>r = np.poly([-1, 1])</code> <code>p = np.poly1d(r)</code>	<code>p = Polynomial.fromroots([-1, 1])</code>
Fit a polynomial of degree <i>deg</i> to data	<code>np.polyfit(x, y, deg)</code>	<code>Polynomial.fit(x, y, deg)</code>
Evaluate a polynomial at a point ²	<code>p(2.0)</code> or <code>np.polyval([1, 2, 3], 2.0)</code>	<code>p(2.0)</code> or <code>polyval(2.0, p.coef)</code> (use <code>p.convert().coef</code> after fit)

Transition Guide

There are significant differences between `numpy.lib.polynomial` and `numpy.polynomial`. The most significant difference is the ordering of the coefficients for the polynomial expressions. The various routines in `numpy.polynomial` all deal with series whose coefficients go from degree zero upward, which is the *reverse order* of the *poly1d* convention. The easy way to remember this is that indices correspond to degree, i.e., `coef[i]` is the coefficient of the term of degree *i*.

Though the difference in convention may be confusing, it is straightforward to convert from the legacy polynomial API to the new. For example, the following demonstrates how you would convert a *numpy.poly1d* instance representing the expression $x^2 + 2x + 3$ to a *Polynomial* instance representing the same expression:

```
>>> import numpy as np
```

```
>>> p1d = np.poly1d([1, 2, 3])
>>> p = np.polynomial.Polynomial(p1d.coef[::-1])
```

In addition to the `coef` attribute, polynomials from the polynomial package also have `domain` and `window` attributes. These attributes are most relevant when fitting polynomials to data, though it should be noted that polynomials with different `domain` and `window` attributes are not considered equal, and can't be mixed in arithmetic:

¹ Note the reversed ordering of the coefficients

² When evaluating polynomials created with `fit()`, use `p(x)` or `polyval(x, p.convert().coef)` to handle domain/window scaling correctly.

```
>>> p1 = np.polynomial.Polynomial([1, 2, 3])
>>> p1
Polynomial([1., 2., 3.], domain=[-1., 1.], window=[-1., 1.], symbol='x')
>>> p2 = np.polynomial.Polynomial([1, 2, 3], domain=[-2, 2])
>>> p1 == p2
False
>>> p1 + p2
Traceback (most recent call last):
...
TypeError: Domains differ
```

See the documentation for the [convenience classes](#) for further details on the domain and window attributes.

Another major difference between the legacy polynomial module and the polynomial package is polynomial fitting. In the old module, fitting was done via the `polyfit` function. In the polynomial package, the `fit` class method is preferred. For example, consider a simple linear fit to the following data:

```
In [1]: rng = np.random.default_rng()

In [2]: x = np.arange(10)

In [3]: y = np.arange(10) + rng.standard_normal(10)
```

With the legacy polynomial module, a linear fit (i.e. polynomial of degree 1) could be applied to these data with `polyfit`:

```
In [4]: np.polyfit(x, y, deg=1)
Out[4]: array([ 1.02069771, -0.33004794])
```

With the new polynomial API, the `fit` class method is preferred:

```
In [5]: p_fitted = np.polynomial.Polynomial.fit(x, y, deg=1)

In [6]: p_fitted
Out[6]: Polynomial([4.26309174, 4.59313969], domain=[0., 9.], window=[-1., 1.],
↪ symbol='x')
```

Note that the coefficients are given *in the scaled domain* defined by the linear mapping between the window and domain. `convert` can be used to get the coefficients in the unscaled data domain.

```
In [7]: p_fitted.convert()
Out[7]: Polynomial([-0.33004794, 1.02069771], domain=[-1., 1.], window=[-1., 1.],
↪ symbol='x')
```

Documentation for the `polynomial` package

In addition to standard power series polynomials, the polynomial package provides several additional kinds of polynomials including Chebyshev, Hermite (two subtypes), Laguerre, and Legendre polynomials. Each of these has an associated *convenience class* available from the `numpy.polynomial` namespace that provides a consistent interface for working with polynomials regardless of their type.

Using the convenience classes

The convenience classes provided by the polynomial package are:

Name	Provides
<i>Polynomial</i>	Power series
<i>Chebyshev</i>	Chebyshev series
<i>Legendre</i>	Legendre series
<i>Laguerre</i>	Laguerre series
<i>Hermite</i>	Hermite series
<i>HermiteE</i>	HermiteE series

The series in this context are finite sums of the corresponding polynomial basis functions multiplied by coefficients. For instance, a power series looks like

$$p(x) = 1 + 2x + 3x^2$$

and has coefficients $[1, 2, 3]$. The Chebyshev series with the same coefficients looks like

$$p(x) = 1T_0(x) + 2T_1(x) + 3T_2(x)$$

and more generally

$$p(x) = \sum_{i=0}^n c_i T_i(x)$$

where in this case the T_n are the Chebyshev functions of degree n , but could just as easily be the basis functions of any of the other classes. The convention for all the classes is that the coefficient $c[i]$ goes with the basis function of degree i .

All of the classes are immutable and have the same methods, and especially they implement the Python numeric operators $+$, $-$, $*$, $//$, $\%$, divmod , $**$, $==$, and $!=$. The last two can be a bit problematic due to floating point roundoff errors. We now give a quick demonstration of the various operations using NumPy version 1.7.0.

Basics

First we need a polynomial class and a polynomial instance to play with. The classes can be imported directly from the polynomial package or from the module of the relevant type. Here we import from the package and use the conventional Polynomial class because of its familiarity:

```
>>> from numpy.polynomial import Polynomial as P
>>> p = P([1, 2, 3])
>>> p
Polynomial([1., 2., 3.], domain=[-1., 1.], window=[-1., 1.], symbol='x')
```

Note that there are three parts to the long version of the printout. The first is the coefficients, the second is the domain, and the third is the window:

```
>>> p.coef
array([1., 2., 3.])
>>> p.domain
array([-1., 1.])
>>> p.window
array([-1., 1.])
```

Printing a polynomial yields the polynomial expression in a more familiar format:

```
>>> print(p)
1.0 + 2.0·x + 3.0·x2
```

Note that the string representation of polynomials uses Unicode characters by default (except on Windows) to express powers and subscripts. An ASCII-based representation is also available (default on Windows). The polynomial string format can be toggled at the package-level with the `set_default_printstyle` function:

```
>>> np.polynomial.set_default_printstyle('ascii')
>>> print(p)
1.0 + 2.0 x + 3.0 x**2
```

or controlled for individual polynomial instances with string formatting:

```
>>> print(f"{p:unicode}")
1.0 + 2.0·x + 3.0·x2
```

We will deal with the domain and window when we get to fitting, for the moment we ignore them and run through the basic algebraic and arithmetic operations.

Addition and Subtraction:

```
>>> p + p
Polynomial([2., 4., 6.], domain=[-1., 1.], window=[-1., 1.], symbol='x')
>>> p - p
Polynomial([0.], domain=[-1., 1.], window=[-1., 1.], symbol='x')
```

Multiplication:

```
>>> p * p
Polynomial([ 1., 4., 10., 12., 9.], domain=[-1., 1.], window=[-1., 1.], symbol='x')
```

Powers:

```
>>> p**2
Polynomial([ 1., 4., 10., 12., 9.], domain=[-1., 1.], window=[-1., 1.], symbol='x')
```

Division:

Floor division, `//`, is the division operator for the polynomial classes, polynomials are treated like integers in this regard. For Python versions < 3.x the `/` operator maps to `//`, as it does for Python, for later versions the `/` will only work for division by scalars. At some point it will be deprecated:

```
>>> p // P([-1, 1])
Polynomial([5., 3.], domain=[-1., 1.], window=[-1., 1.], symbol='x')
```

Remainder:

```
>>> p % P([-1, 1])
Polynomial([6.], domain=[-1., 1.], window=[-1., 1.], symbol='x')
```

Divmod:

```
>>> quo, rem = divmod(p, P([-1, 1]))
>>> quo
```

(continues on next page)

(continued from previous page)

```
Polynomial([5., 3.], domain=[-1., 1.], window=[-1., 1.], symbol='x')
>>> rem
Polynomial([6.], domain=[-1., 1.], window=[-1., 1.], symbol='x')
```

Evaluation:

```
>>> x = np.arange(5)
>>> p(x)
array([ 1.,  6., 17., 34., 57.])
>>> x = np.arange(6).reshape(3,2)
>>> p(x)
array([[ 1.,  6.],
       [17., 34.],
       [57., 86.]])
```

Substitution:

Substitute a polynomial for x and expand the result. Here we substitute p in itself leading to a new polynomial of degree 4 after expansion. If the polynomials are regarded as functions this is composition of functions:

```
>>> p(p)
Polynomial([ 6., 16., 36., 36., 27.], domain=[-1., 1.], window=[-1., 1.], symbol='x
↪')
```

Roots:

```
>>> p.roots()
array([-0.33333333-0.47140452j, -0.33333333+0.47140452j])
```

It isn't always convenient to explicitly use Polynomial instances, so tuples, lists, arrays, and scalars are automatically cast in the arithmetic operations:

```
>>> p + [1, 2, 3]
Polynomial([2., 4., 6.], domain=[-1., 1.], window=[-1., 1.], symbol='x')
>>> [1, 2, 3] * p
Polynomial([ 1.,  4., 10., 12.,  9.], domain=[-1., 1.], window=[-1., 1.], symbol='x
↪')
>>> p / 2
Polynomial([0.5, 1. , 1.5], domain=[-1., 1.], window=[-1., 1.], symbol='x')
```

Polynomials that differ in domain, window, or class can't be mixed in arithmetic:

```
>>> from numpy.polynomial import Chebyshev as T
>>> p + P([1], domain=[0,1])
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
  File "<string>", line 213, in __add__
TypeError: Domains differ
>>> p + P([1], window=[0,1])
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
  File "<string>", line 215, in __add__
TypeError: Windows differ
>>> p + T([1])
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
```

(continues on next page)

(continued from previous page)

```
File "<string>", line 211, in __add__
TypeError: Polynomial types differ
```

But different types can be used for substitution. In fact, this is how conversion of Polynomial classes among themselves is done for type, domain, and window casting:

```
>>> p(T([0, 1]))
Chebyshev([2.5, 2., 1.5], domain=[-1., 1.], window=[-1., 1.], symbol='x')
```

Which gives the polynomial p in Chebyshev form. This works because $T_1(x) = x$ and substituting x for x doesn't change the original polynomial. However, all the multiplications and divisions will be done using Chebyshev series, hence the type of the result.

It is intended that all polynomial instances are immutable, therefore augmented operations ($+=$, $-=$, etc.) and any other functionality that would violate the immutability of a polynomial instance are intentionally unimplemented.

Calculus

Polynomial instances can be integrated and differentiated.:

```
>>> from numpy.polynomial import Polynomial as P
>>> p = P([2, 6])
>>> p.integ()
Polynomial([0., 2., 3.], domain=[-1., 1.], window=[-1., 1.], symbol='x')
>>> p.integ(2)
Polynomial([0., 0., 1., 1.], domain=[-1., 1.], window=[-1., 1.], symbol='x')
```

The first example integrates p once, the second example integrates it twice. By default, the lower bound of the integration and the integration constant are 0, but both can be specified.:

```
>>> p.integ(lbnd=-1)
Polynomial([-1., 2., 3.], domain=[-1., 1.], window=[-1., 1.], symbol='x')
>>> p.integ(lbnd=-1, k=1)
Polynomial([0., 2., 3.], domain=[-1., 1.], window=[-1., 1.], symbol='x')
```

In the first case the lower bound of the integration is set to -1 and the integration constant is 0. In the second the constant of integration is set to 1 as well. Differentiation is simpler since the only option is the number of times the polynomial is differentiated:

```
>>> p = P([1, 2, 3])
>>> p.deriv(1)
Polynomial([2., 6.], domain=[-1., 1.], window=[-1., 1.], symbol='x')
>>> p.deriv(2)
Polynomial([6.], domain=[-1., 1.], window=[-1., 1.], symbol='x')
```

Other polynomial constructors

Constructing polynomials by specifying coefficients is just one way of obtaining a polynomial instance, they may also be created by specifying their roots, by conversion from other polynomial types, and by least squares fits. Fitting is discussed in its own section, the other methods are demonstrated below:

```
>>> from numpy.polynomial import Polynomial as P
>>> from numpy.polynomial import Chebyshev as T
>>> p = P.fromroots([1, 2, 3])
>>> p
Polynomial([-6., 11., -6., 1.], domain=[-1., 1.], window=[-1., 1.], symbol='x')
>>> p.convert(kind=T)
Chebyshev([-9. , 11.75, -3. , 0.25], domain=[-1., 1.], window=[-1., 1.], symbol='x')
↪ 'x')
```

The convert method can also convert domain and window:

```
>>> p.convert(kind=T, domain=[0, 1])
Chebyshev([-2.4375 , 2.96875, -0.5625 , 0.03125], domain=[0., 1.], window=[-1., 1.], symbol='x')
↪ , symbol='x')
>>> p.convert(kind=P, domain=[0, 1])
Polynomial([-1.875, 2.875, -1.125, 0.125], domain=[0., 1.], window=[-1., 1.], symbol='x')
↪ symbol='x')
```

In numpy versions $\geq 1.7.0$ the *basis* and *cast* class methods are also available. The cast method works like the convert method while the basis method returns the basis polynomial of given degree:

```
>>> P.basis(3)
Polynomial([0., 0., 0., 1.], domain=[-1., 1.], window=[-1., 1.], symbol='x')
>>> T.cast(p)
Chebyshev([-9. , 11.75, -3. , 0.25], domain=[-1., 1.], window=[-1., 1.], symbol='x')
↪ 'x')
```

Conversions between types can be useful, but it is *not* recommended for routine use. The loss of numerical precision in passing from a Chebyshev series of degree 50 to a Polynomial series of the same degree can make the results of numerical evaluation essentially random.

Fitting

Fitting is the reason that the *domain* and *window* attributes are part of the convenience classes. To illustrate the problem, the values of the Chebyshev polynomials up to degree 5 are plotted below.

```
>>> import matplotlib.pyplot as plt
>>> from numpy.polynomial import Chebyshev as T
>>> x = np.linspace(-1, 1, 100)
>>> for i in range(6):
...     ax = plt.plot(x, T.basis(i)(x), lw=2, label=f"$T_{i}$")
...
>>> plt.legend(loc="upper left")
>>> plt.show()
```

In the range $-1 \leq x \leq 1$ they are nice, equiripple functions lying between ± 1 . The same plots over the range $-2 \leq x \leq 2$ look very different:

```
>>> import matplotlib.pyplot as plt
>>> from numpy.polynomial import Chebyshev as T
>>> x = np.linspace(-2, 2, 100)
>>> for i in range(6):
...     ax = plt.plot(x, T.basis(i)(x), lw=2, label=f"$T_{i}$")
...
>>> plt.legend(loc="lower right")
>>> plt.show()
```

As can be seen, the “good” parts have shrunk to insignificance. In using Chebyshev polynomials for fitting we want to use the region where x is between -1 and 1 and that is what the *window* specifies. However, it is unlikely that the data to be fit has all its data points in that interval, so we use *domain* to specify the interval where the data points lie. When the fit is done, the domain is first mapped to the window by a linear transformation and the usual least squares fit is done using the mapped data points. The window and domain of the fit are part of the returned series and are automatically used when computing values, derivatives, and such. If they aren’t specified in the call the fitting routine will use the default window

and the smallest domain that holds all the data points. This is illustrated below for a fit to a noisy sine curve.

```
>>> import numpy as np
>>> import matplotlib.pyplot as plt
>>> from numpy.polynomial import Chebyshev as T
>>> np.random.seed(11)
>>> x = np.linspace(0, 2*np.pi, 20)
>>> y = np.sin(x) + np.random.normal(scale=.1, size=x.shape)
>>> p = T.fit(x, y, 5)
>>> plt.plot(x, y, 'o')
>>> xx, yy = p.linspace()
>>> plt.plot(xx, yy, lw=2)
>>> p.domain
array([0.          ,  6.28318531])
>>> p.window
array([-1.,  1.])
>>> plt.show()
```

Documentation pertaining to specific functions defined for each kind of polynomial individually can be found in the corresponding module documentation:

Power Series (`numpy.polynomial.polynomial`)

This module provides a number of objects (mostly functions) useful for dealing with polynomials, including a *Polynomial* class that encapsulates the usual arithmetic operations. (General information on how this module represents and works with polynomial objects is in the docstring for its “parent” sub-package, `numpy.polynomial`).

Classes

<i>Polynomial</i> (coef[, domain, window, symbol])	A power series class.
--	-----------------------

class `numpy.polynomial.polynomial.Polynomial` (*coef*, *domain=None*, *window=None*, *symbol='x'*)

A power series class.

The Polynomial class provides the standard Python numerical methods '+', '-', '*', '//', '%', 'divmod', '**', and '()' as well as the attributes and methods listed below.

Parameters

coef

[array_like] Polynomial coefficients in order of increasing degree, i.e., (1, 2, 3) give $1 + 2*x + 3*x**2$.

domain

[(2,) array_like, optional] Domain to use. The interval `[domain[0], domain[1]]` is mapped to the interval `[window[0], window[1]]` by shifting and scaling. The default value is `[-1., 1.]`.

window

[(2,) array_like, optional] Window, see `domain` for its use. The default value is `[-1., 1.]`.

symbol

[str, optional] Symbol used to represent the independent variable in string representations of the polynomial expression, e.g. for printing. The symbol must be a valid Python identifier. Default value is 'x'.

New in version 1.24.

Attributes

basis_name

symbol

Methods

<code>__call__(arg)</code>	Call self as a function.
<code>basis(deg[, domain, window, symbol])</code>	Series basis polynomial of degree <i>deg</i> .
<code>cast(series[, domain, window])</code>	Convert series to series of this class.
<code>convert([domain, kind, window])</code>	Convert series to a different kind and/or domain and/or window.
<code>copy()</code>	Return a copy.
<code>cutdeg(deg)</code>	Truncate series to the given degree.
<code>degree()</code>	The degree of the series.
<code>deriv([m])</code>	Differentiate.
<code>fit(x, y, deg[, domain, rcond, full, w, ...])</code>	Least squares fit to data.
<code>fromroots(roots[, domain, window, symbol])</code>	Return series instance that has the specified roots.
<code>has_samecoef(other)</code>	Check if coefficients match.
<code>has_samedomain(other)</code>	Check if domains match.
<code>has_sametype(other)</code>	Check if types match.
<code>has_samewindow(other)</code>	Check if windows match.
<code>identity([domain, window, symbol])</code>	Identity function.
<code>integ([m, k, lbnd])</code>	Integrate.
<code>linspace([n, domain])</code>	Return x, y values at equally spaced points in domain.
<code>mapparms()</code>	Return the mapping parameters.
<code>roots()</code>	Return the roots of the series polynomial.
<code>trim([tol])</code>	Remove trailing coefficients
<code>truncate(size)</code>	Truncate series to length <i>size</i> .

method

`polynomial.polynomial.Polynomial.__call__(arg)`

Call self as a function.

method

classmethod `polynomial.polynomial.Polynomial.basis(deg, domain=None, window=None, symbol='x')`

Series basis polynomial of degree *deg*.

Returns the series representing the basis polynomial of degree *deg*.

Parameters

deg

[int] Degree of the basis polynomial for the series. Must be ≥ 0 .

domain

[{None, array_like}, optional] If given, the array must be of the form `[beg, end]`, where *beg* and *end* are the endpoints of the domain. If None is given then the class domain is used. The default is None.

window

[{None, array_like}, optional] If given, the resulting array must be if the form `[beg, end]`, where *beg* and *end* are the endpoints of the window. If None is given then the class window is used. The default is None.

symbol

[str, optional] Symbol representing the independent variable. Default is 'x'.

Returns

new_series

[series] A series with the coefficient of the *deg* term set to one and all others zero.

method

classmethod `polynomial.polynomial.Polynomial.cast` (*series*, *domain=None*,
window=None)

Convert series to series of this class.

The *series* is expected to be an instance of some polynomial series of one of the types supported by the `numpy.polynomial` module, but could be some other class that supports the convert method.

Parameters**series**

[series] The series instance to be converted.

domain

[{None, array_like}, optional] If given, the array must be of the form `[beg, end]`, where `beg` and `end` are the endpoints of the domain. If `None` is given then the class domain is used. The default is `None`.

window

[{None, array_like}, optional] If given, the resulting array must be of the form `[beg, end]`, where `beg` and `end` are the endpoints of the window. If `None` is given then the class window is used. The default is `None`.

Returns**new_series**

[series] A series of the same kind as the calling class and equal to *series* when evaluated.

See also:

convert

similar instance method

method

`polynomial.polynomial.Polynomial.convert` (*domain=None*, *kind=None*, *window=None*)

Convert series to a different kind and/or domain and/or window.

Parameters**domain**

[array_like, optional] The domain of the converted series. If the value is `None`, the default domain of *kind* is used.

kind

[class, optional] The polynomial series type class to which the current instance should be converted. If *kind* is `None`, then the class of the current instance is used.

window

[array_like, optional] The window of the converted series. If the value is `None`, the default window of *kind* is used.

Returns**new_series**

[series] The returned class can be of different type than the current instance and/or have a different domain and/or different window.

Notes

Conversion between domains and class types can result in numerically ill defined series.

method

```
polynomial.polynomial.Polynomial.copy()
```

Return a copy.

Returns

new_series

[series] Copy of self.

method

```
polynomial.polynomial.Polynomial.cutdeg(deg)
```

Truncate series to the given degree.

Reduce the degree of the series to *deg* by discarding the high order terms. If *deg* is greater than the current degree a copy of the current series is returned. This can be useful in least squares where the coefficients of the high degree terms may be very small.

Parameters

deg

[non-negative int] The series is reduced to degree *deg* by discarding the high order terms. The value of *deg* must be a non-negative integer.

Returns

new_series

[series] New instance of series with reduced degree.

method

```
polynomial.polynomial.Polynomial.degree()
```

The degree of the series.

Returns

degree

[int] Degree of the series, one less than the number of coefficients.

Examples

Create a polynomial object for $1 + 7x + 4x^2$:

```
>>> np.polynomial.set_default_printstyle("unicode")
>>> poly = np.polynomial.Polynomial([1, 7, 4])
>>> print(poly)
1.0 + 7.0·x + 4.0·x2
>>> poly.degree()
2
```

Note that this method does not check for non-zero coefficients. You must trim the polynomial to remove any trailing zeroes:

```

>>> poly = np.polynomial.Polynomial([1, 7, 0])
>>> print(poly)
1.0 + 7.0·x + 0.0·x2
>>> poly.degree()
2
>>> poly.trim().degree()
1

```

method

`polynomial.polynomial.Polynomial.deriv(m=1)`

Differentiate.

Return a series instance of that is the derivative of the current series.

Parameters

m

[non-negative int] Find the derivative of order *m*.

Returns

new_series

[series] A new series representing the derivative. The domain is the same as the domain of the differentiated series.

method

classmethod `polynomial.polynomial.Polynomial.fit(x, y, deg, domain=None, rcond=None, full=False, w=None, window=None, symbol='x')`

Least squares fit to data.

Return a series instance that is the least squares fit to the data *y* sampled at *x*. The domain of the returned instance can be specified and this will often result in a superior fit with less chance of ill conditioning.

Parameters

x

[array_like, shape (M,)] x-coordinates of the M sample points (*x*[*i*], *y*[*i*]).

y

[array_like, shape (M,)] y-coordinates of the M sample points (*x*[*i*], *y*[*i*]).

deg

[int or 1-D array_like] Degree(s) of the fitting polynomials. If *deg* is a single integer all terms up to and including the *deg*'th term are included in the fit. For NumPy versions $\geq 1.11.0$ a list of integers specifying the degrees of the terms to include may be used instead.

domain

[{None, [beg, end], []}, optional] Domain to use for the returned series. If *None*, then a minimal domain that covers the points *x* is chosen. If [] the class domain is used. The default value was the class domain in NumPy 1.4 and *None* in later versions. The [] option was added in numpy 1.5.0.

rcond

[float, optional] Relative condition number of the fit. Singular values smaller than this relative to the largest singular value will be ignored. The default value is `len(x)*eps`, where *eps* is the relative precision of the float type, about 2e-16 in most cases.

full

[bool, optional] Switch determining nature of return value. When it is False (the default) just the coefficients are returned, when True diagnostic information from the singular value decomposition is also returned.

w

[array_like, shape (M,), optional] Weights. If not None, the weight $w[i]$ applies to the unsquared residual $y[i] - \hat{y}[i]$ at $x[i]$. Ideally the weights are chosen so that the errors of the products $w[i] * y[i]$ all have the same variance. When using inverse-variance weighting, use $w[i] = 1/\text{sigma}(y[i])$. The default value is None.

window

[[[beg, end]], optional] Window to use for the returned series. The default value is the default class domain

symbol

[str, optional] Symbol representing the independent variable. Default is 'x'.

Returns**new_series**

[series] A series that represents the least squares fit to the data and has the domain and window specified in the call. If the coefficients for the unscaled and unshifted basis polynomials are of interest, do `new_series.convert().coef`.

[resid, rank, sv, rcond]

[list] These values are only returned if `full == True`

- resid – sum of squared residuals of the least squares fit
- rank – the numerical rank of the scaled Vandermonde matrix
- sv – singular values of the scaled Vandermonde matrix
- rcond – value of *rcond*.

For more details, see [*linalg.lstsq*](#).

method

classmethod `polynomial.polynomial.Polynomial.fromroots` (*roots*, *domain*=[],
window=None, *symbol*='x')

Return series instance that has the specified roots.

Returns a series representing the product $(x - r[0]) * (x - r[1]) * \dots * (x - r[n-1])$, where *r* is a list of roots.

Parameters**roots**

[array_like] List of roots.

domain

[[[], None, array_like], optional] Domain for the resulting series. If None the domain is the interval from the smallest root to the largest. If [] the domain is the class domain. The default is [].

window

[{None, array_like}, optional] Window for the returned series. If None the class window is used. The default is None.

symbol

[str, optional] Symbol representing the independent variable. Default is 'x'.

Returns**new_series**

[series] Series with the specified roots.

method

`polynomial.polynomial.Polynomial.has_samecoef(other)`

Check if coefficients match.

Parameters**other**

[class instance] The other class must have the `coef` attribute.

Returns**bool**

[boolean] True if the coefficients are the same, False otherwise.

method

`polynomial.polynomial.Polynomial.has_samedomain(other)`

Check if domains match.

Parameters**other**

[class instance] The other class must have the `domain` attribute.

Returns**bool**

[boolean] True if the domains are the same, False otherwise.

method

`polynomial.polynomial.Polynomial.has_sametype(other)`

Check if types match.

Parameters**other**

[object] Class instance.

Returns**bool**

[boolean] True if other is same class as self

method

`polynomial.polynomial.Polynomial.has_samewindow(other)`

Check if windows match.

Parameters**other**

[class instance] The other class must have the `window` attribute.

Returns**bool**

[boolean] True if the windows are the same, False otherwise.

method

classmethod `polynomial.polynomial.Polynomial.identity` (*domain=None, window=None, symbol='x'*)

Identity function.

If p is the returned series, then $p(x) == x$ for all values of x .

Parameters

domain

[*None*, array_like], optional] If given, the array must be of the form [*beg*, *end*], where *beg* and *end* are the endpoints of the domain. If *None* is given then the class domain is used. The default is *None*.

window

[*None*, array_like], optional] If given, the resulting array must be if the form [*beg*, *end*], where *beg* and *end* are the endpoints of the window. If *None* is given then the class window is used. The default is *None*.

symbol

[str, optional] Symbol representing the independent variable. Default is 'x'.

Returns

new_series

[series] Series of representing the identity.

method

`polynomial.polynomial.Polynomial.integ` (*m=1, k=[], lbnd=None*)

Integrate.

Return a series instance that is the definite integral of the current series.

Parameters

m

[non-negative int] The number of integrations to perform.

k

[array_like] Integration constants. The first constant is applied to the first integration, the second to the second, and so on. The list of values must less than or equal to *m* in length and any missing values are set to zero.

lbnd

[Scalar] The lower bound of the definite integral.

Returns

new_series

[series] A new series representing the integral. The domain is the same as the domain of the integrated series.

method

`polynomial.polynomial.Polynomial.linspace` (*n=100, domain=None*)

Return x , y values at equally spaced points in domain.

Returns the x , y values at n linearly spaced points across the domain. Here y is the value of the polynomial at the points x . By default the domain is the same as that of the series instance. This method is intended mostly as a plotting aid.

Parameters

n

[int, optional] Number of point pairs to return. The default value is 100.

domain[None, array_like], optional] If not None, the specified domain is used instead of that of the calling instance. It should be of the form `[beg, end]`. The default is None which case the class domain is used.**Returns****x, y**[ndarray] x is equal to `linspace(self.domain[0], self.domain[1], n)` and y is the series evaluated at element of x.

method

`polynomial.polynomial.Polynomial.mapparms()`

Return the mapping parameters.

The returned values define a linear map $\text{off} + \text{scl} * x$ that is applied to the input arguments before the series is evaluated. The map depends on the `domain` and `window`; if the current domain is equal to the window the resulting map is the identity. If the coefficients of the series instance are to be used by themselves outside this class, then the linear function must be substituted for the `x` in the standard representation of the base polynomials.

Returns**off, scl**[float or complex] The mapping function is defined by $\text{off} + \text{scl} * x$.**Notes**

If the current domain is the interval $[l1, r1]$ and the window is $[l2, r2]$, then the linear mapping function L is defined by the equations:

$$\begin{aligned} L(l1) &= l2 \\ L(r1) &= r2 \end{aligned}$$

method

`polynomial.polynomial.Polynomial.roots()`

Return the roots of the series polynomial.

Compute the roots for the series. Note that the accuracy of the roots decreases the further outside the domain they lie.

Returns**roots**

[ndarray] Array containing the roots of the series.

method

`polynomial.polynomial.Polynomial.trim(tol=0)`

Remove trailing coefficients

Remove trailing coefficients until a coefficient is reached whose absolute value greater than `tol` or the beginning of the series is reached. If all the coefficients would be removed the series is set to `[0]`. A new series instance is returned with the new coefficients. The current instance remains unchanged.

Parameters

tol
[non-negative number.] All trailing coefficients less than *tol* will be removed.

Returns

new_series
[series] New instance of series with trimmed coefficients.

method

`polynomial.polynomial.Polynomial.truncate(size)`

Truncate series to length *size*.

Reduce the series to length *size* by discarding the high degree terms. The value of *size* must be a positive integer. This can be useful in least squares where the coefficients of the high degree terms may be very small.

Parameters

size
[positive int] The series is reduced to length *size* by discarding the high degree terms. The value of *size* must be a positive integer.

Returns

new_series
[series] New instance of series with truncated coefficients.

Constants

<i>polydomain</i>	<code>ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None)</code>
<i>polyzero</i>	<code>ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None)</code>
<i>polyone</i>	<code>ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None)</code>
<i>polyx</i>	<code>ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None)</code>

`polynomial.polynomial.polydomain = array([-1., 1.])`

`ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None) –`

`ndarray(shape, dtype=np.float64, buffer=None, offset=0, strides=None, order=None)`

An array object represents a multidimensional, homogeneous array of fixed-size items. An associated data-type object describes the format of each element in the array (its byte-order, how many bytes it occupies in memory, whether it is an integer, a floating point number, or something else, etc.)

Arrays should be constructed using *array*, *zeros* or *empty* (refer to the See Also section below). The parameters given here refer to a low-level method (*ndarray(...)*) for instantiating an array.

For more information, refer to the *numpy* module and examine the methods and attributes of an array.

Parameters

(for the `__new__` method; see Notes below)

shape
[tuple of ints] Shape of created array.

dtype

[data-type, optional] Any object that can be interpreted as a numpy data type. Default is `numpy.float64`.

buffer

[object exposing buffer interface, optional] Used to fill the array with data.

offset

[int, optional] Offset of array data in buffer.

strides

[tuple of ints, optional] Strides of data in memory.

order

[{'C', 'F'}, optional] Row-major (C-style) or column-major (Fortran-style) order.

Attributes**T**

[ndarray] Transpose of the array.

data

[buffer] The array's elements, in memory.

dtype

[dtype object] Describes the format of the elements in the array.

flags

[dict] Dictionary containing information related to memory use, e.g., 'C_CONTIGUOUS', 'OWNDATA', 'WRITEABLE', etc.

flat

[numpy.flatiter object] Flattened version of the array as an iterator. The iterator allows assignments, e.g., `x.flat = 3` (See `ndarray.flat` for assignment examples; TODO).

imag

[ndarray] Imaginary part of the array.

real

[ndarray] Real part of the array.

size

[int] Number of elements in the array.

itemsize

[int] The memory use of each array element in bytes.

nbytes

[int] The total number of bytes required to store the array data, i.e., `itemsize * size`.

ndim

[int] The array's number of dimensions.

shape

[tuple of ints] Shape of the array.

strides

[tuple of ints] The step-size required to move from one element to the next in memory. For example, a contiguous (3, 4) array of type `int16` in C-order has strides (8, 2). This implies that to move from element to element in memory requires jumps of 2 bytes. To move from row-to-row, one needs to jump 8 bytes at a time (2 * 4).

ctypes

[ctypes object] Class containing properties of the array needed for interaction with ctypes.

base

[ndarray] If the array is a view into another array, that array is its *base* (unless that array is also a view). The *base* array is where the array data is actually stored.

See also:**array**

Construct an array.

zeros

Create an array, each element of which is zero.

empty

Create an array, but leave its allocated memory unchanged (i.e., it contains “garbage”).

dtype

Create a data-type.

numpy.typing.NDArray

An ndarray alias *generic* w.r.t. its *dtype.type*.

Notes

There are two modes of creating an array using `__new__`:

1. If *buffer* is None, then only *shape*, *dtype*, and *order* are used.
2. If *buffer* is an object exposing the buffer interface, then all keywords are interpreted.

No `__init__` method is needed because the array is fully initialized after the `__new__` method.

Examples

These examples illustrate the low-level *ndarray* constructor. Refer to the *See Also* section above for easier ways of constructing an ndarray.

First mode, *buffer* is None:

```
>>> import numpy as np
>>> np.ndarray(shape=(2,2), dtype=np.float64, order='F')
array([[0.0e+000, 0.0e+000], # random
       [      nan, 2.5e-323]])
```

Second mode:

```
>>> np.ndarray((2,), buffer=np.array([1,2,3]),
...           offset=np.int_().itemsize,
...           dtype=np.int_) # offset = 1*itemsize, i.e. skip first element
array([2, 3])
```

```
polynomial.polynomial.polyzero = array([0])
```

```
ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None) –
```

```
ndarray(shape, dtype=np.float64, buffer=None, offset=0, strides=None, order=None)
```

An array object represents a multidimensional, homogeneous array of fixed-size items. An associated data-type object describes the format of each element in the array (its byte-order, how many bytes it occupies in memory, whether it is an integer, a floating point number, or something else, etc.)

Arrays should be constructed using `array`, `zeros` or `empty` (refer to the See Also section below). The parameters given here refer to a low-level method (`ndarray(...)`) for instantiating an array.

For more information, refer to the `numpy` module and examine the methods and attributes of an array.

Parameters

(for the `__new__` method; see Notes below)

shape

[tuple of ints] Shape of created array.

dtype

[data-type, optional] Any object that can be interpreted as a numpy data type. Default is `numpy.float64`.

buffer

[object exposing buffer interface, optional] Used to fill the array with data.

offset

[int, optional] Offset of array data in buffer.

strides

[tuple of ints, optional] Strides of data in memory.

order

[['C', 'F'], optional] Row-major (C-style) or column-major (Fortran-style) order.

Attributes

T

[ndarray] Transpose of the array.

data

[buffer] The array's elements, in memory.

dtype

[dtype object] Describes the format of the elements in the array.

flags

[dict] Dictionary containing information related to memory use, e.g., 'C_CONTIGUOUS', 'OWNDATA', 'WRITEABLE', etc.

flat

[numpy.flatiter object] Flattened version of the array as an iterator. The iterator allows assignments, e.g., `x.flat = 3` (See `ndarray.flat` for assignment examples; TODO).

imag

[ndarray] Imaginary part of the array.

real

[ndarray] Real part of the array.

size

[int] Number of elements in the array.

itemsize

[int] The memory use of each array element in bytes.

nbytes

[int] The total number of bytes required to store the array data, i.e., `itemsize * size`.

ndim

[int] The array's number of dimensions.

shape

[tuple of ints] Shape of the array.

strides

[tuple of ints] The step-size required to move from one element to the next in memory. For example, a contiguous (3, 4) array of type `int16` in C-order has strides (8, 2). This implies that to move from element to element in memory requires jumps of 2 bytes. To move from row-to-row, one needs to jump 8 bytes at a time ($2 * 4$).

ctypes

[ctypes object] Class containing properties of the array needed for interaction with ctypes.

base

[ndarray] If the array is a view into another array, that array is its *base* (unless that array is also a view). The *base* array is where the array data is actually stored.

See also:***array***

Construct an array.

zeros

Create an array, each element of which is zero.

empty

Create an array, but leave its allocated memory unchanged (i.e., it contains “garbage”).

dtype

Create a data-type.

numpy.typing.NDArray

An ndarray alias *generic* w.r.t. its *dtype.type*.

Notes

There are two modes of creating an array using `__new__`:

1. If *buffer* is None, then only *shape*, *dtype*, and *order* are used.
2. If *buffer* is an object exposing the buffer interface, then all keywords are interpreted.

No `__init__` method is needed because the array is fully initialized after the `__new__` method.

Examples

These examples illustrate the low-level *ndarray* constructor. Refer to the *See Also* section above for easier ways of constructing an ndarray.

First mode, *buffer* is None:

```
>>> import numpy as np
>>> np.ndarray(shape=(2,2), dtype=np.float64, order='F')
array([[0.0e+000, 0.0e+000], # random
       [      nan, 2.5e-323]])
```

Second mode:

```
>>> np.ndarray((2,), buffer=np.array([1,2,3]),
...           offset=np.int_().itemsize,
...           dtype=np.int_) # offset = 1*itemsize, i.e. skip first element
array([2, 3])
```

```
polynomial.polynomial.polyone = array([1])
```

```
ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None) -
```

```
ndarray(shape, dtype=np.float64, buffer=None, offset=0, strides=None, order=None)
```

An array object represents a multidimensional, homogeneous array of fixed-size items. An associated data-type object describes the format of each element in the array (its byte-order, how many bytes it occupies in memory, whether it is an integer, a floating point number, or something else, etc.)

Arrays should be constructed using *array*, *zeros* or *empty* (refer to the See Also section below). The parameters given here refer to a low-level method (*ndarray(...)*) for instantiating an array.

For more information, refer to the *numpy* module and examine the methods and attributes of an array.

Parameters

(for the `__new__` method; see Notes below)

shape

[tuple of ints] Shape of created array.

dtype

[data-type, optional] Any object that can be interpreted as a numpy data type. Default is *numpy.float64*.

buffer

[object exposing buffer interface, optional] Used to fill the array with data.

offset

[int, optional] Offset of array data in buffer.

strides

[tuple of ints, optional] Strides of data in memory.

order

[['C', 'F'], optional] Row-major (C-style) or column-major (Fortran-style) order.

Attributes

T

[ndarray] Transpose of the array.

data

[buffer] The array's elements, in memory.

dtype

[dtype object] Describes the format of the elements in the array.

flags

[dict] Dictionary containing information related to memory use, e.g., 'C_CONTIGUOUS', 'OWNDATA', 'WRITEABLE', etc.

flat

[numpy.flatiter object] Flattened version of the array as an iterator. The iterator allows assignments, e.g., `x.flat = 3` (See *ndarray.flat* for assignment examples; TODO).

imag

[ndarray] Imaginary part of the array.

real

[ndarray] Real part of the array.

size

[int] Number of elements in the array.

itemsize

[int] The memory use of each array element in bytes.

nbytes

[int] The total number of bytes required to store the array data, i.e., `itemsize * size`.

ndim

[int] The array's number of dimensions.

shape

[tuple of ints] Shape of the array.

strides

[tuple of ints] The step-size required to move from one element to the next in memory. For example, a contiguous (3, 4) array of type `int16` in C-order has strides (8, 2). This implies that to move from element to element in memory requires jumps of 2 bytes. To move from row-to-row, one needs to jump 8 bytes at a time (2 * 4).

ctypes

[ctypes object] Class containing properties of the array needed for interaction with ctypes.

base

[ndarray] If the array is a view into another array, that array is its *base* (unless that array is also a view). The *base* array is where the array data is actually stored.

See also:**`array`**

Construct an array.

`zeros`

Create an array, each element of which is zero.

`empty`

Create an array, but leave its allocated memory unchanged (i.e., it contains “garbage”).

`dtype`

Create a data-type.

`numpy.typing.NDArray`

An ndarray alias *generic* w.r.t. its `dtype.type`.

Notes

There are two modes of creating an array using `__new__`:

1. If *buffer* is None, then only *shape*, *dtype*, and *order* are used.
2. If *buffer* is an object exposing the buffer interface, then all keywords are interpreted.

No `__init__` method is needed because the array is fully initialized after the `__new__` method.

Examples

These examples illustrate the low-level `ndarray` constructor. Refer to the *See Also* section above for easier ways of constructing an ndarray.

First mode, *buffer* is None:

```
>>> import numpy as np
>>> np.ndarray(shape=(2,2), dtype=np.float64, order='F')
array([[0.0e+000, 0.0e+000], # random
       [      nan, 2.5e-323]])
```

Second mode:

```
>>> np.ndarray((2,), buffer=np.array([1,2,3]),
...           offset=np.int_().itemsize,
...           dtype=np.int_) # offset = 1*itemsize, i.e. skip first element
array([2, 3])
```

```
polynomial.polynomial.polyx = array([0, 1])
```

```
ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None) -
```

```
ndarray(shape, dtype=np.float64, buffer=None, offset=0, strides=None, order=None)
```

An array object represents a multidimensional, homogeneous array of fixed-size items. An associated data-type object describes the format of each element in the array (its byte-order, how many bytes it occupies in memory, whether it is an integer, a floating point number, or something else, etc.)

Arrays should be constructed using `array`, `zeros` or `empty` (refer to the *See Also* section below). The parameters given here refer to a low-level method (`ndarray(...)`) for instantiating an array.

For more information, refer to the `numpy` module and examine the methods and attributes of an array.

Parameters

(for the `__new__` method; see Notes below)

shape

[tuple of ints] Shape of created array.

dtype

[data-type, optional] Any object that can be interpreted as a numpy data type. Default is `numpy.float64`.

buffer

[object exposing buffer interface, optional] Used to fill the array with data.

offset

[int, optional] Offset of array data in buffer.

strides

[tuple of ints, optional] Strides of data in memory.

order

[{'C', 'F'}, optional] Row-major (C-style) or column-major (Fortran-style) order.

Attributes

T

[ndarray] Transpose of the array.

data

[buffer] The array's elements, in memory.

dtype

[dtype object] Describes the format of the elements in the array.

flags

[dict] Dictionary containing information related to memory use, e.g., 'C_CONTIGUOUS', 'OWNDATA', 'WRITEABLE', etc.

flat

[numpy.flatiter object] Flattened version of the array as an iterator. The iterator allows assignments, e.g., `x.flat = 3` (See [ndarray.flat](#) for assignment examples; TODO).

imag

[ndarray] Imaginary part of the array.

real

[ndarray] Real part of the array.

size

[int] Number of elements in the array.

itemsize

[int] The memory use of each array element in bytes.

nbytes

[int] The total number of bytes required to store the array data, i.e., `itemsize * size`.

ndim

[int] The array's number of dimensions.

shape

[tuple of ints] Shape of the array.

strides

[tuple of ints] The step-size required to move from one element to the next in memory. For example, a contiguous (3, 4) array of type `int16` in C-order has strides (8, 2). This implies that to move from element to element in memory requires jumps of 2 bytes. To move from row-to-row, one needs to jump 8 bytes at a time (2 * 4).

ctypes

[ctypes object] Class containing properties of the array needed for interaction with ctypes.

base

[ndarray] If the array is a view into another array, that array is its *base* (unless that array is also a view). The *base* array is where the array data is actually stored.

See also:**`array`**

Construct an array.

`zeros`

Create an array, each element of which is zero.

`empty`

Create an array, but leave its allocated memory unchanged (i.e., it contains "garbage").

`dtype`

Create a data-type.

`numpy.typing.NDArray`

An ndarray alias *generic* w.r.t. its `dtype.type`.

Notes

There are two modes of creating an array using `__new__`:

1. If *buffer* is None, then only *shape*, *dtype*, and *order* are used.
2. If *buffer* is an object exposing the buffer interface, then all keywords are interpreted.

No `__init__` method is needed because the array is fully initialized after the `__new__` method.

Examples

These examples illustrate the low-level *ndarray* constructor. Refer to the *See Also* section above for easier ways of constructing an ndarray.

First mode, *buffer* is None:

```
>>> import numpy as np
>>> np.ndarray(shape=(2,2), dtype=np.float64, order='F')
array([[0.0e+000, 0.0e+000], # random
       [      nan, 2.5e-323]])
```

Second mode:

```
>>> np.ndarray((2,), buffer=np.array([1,2,3]),
...           offset=np.int_().itemsize,
...           dtype=np.int_) # offset = 1*itemsize, i.e. skip first element
array([2, 3])
```

Arithmetic

<i>polyadd</i> (c1, c2)	Add one polynomial to another.
<i>polysub</i> (c1, c2)	Subtract one polynomial from another.
<i>polymulx</i> (c)	Multiply a polynomial by x.
<i>polymul</i> (c1, c2)	Multiply one polynomial by another.
<i>polydiv</i> (c1, c2)	Divide one polynomial by another.
<i>polypow</i> (c, pow[, maxpower])	Raise a polynomial to a power.
<i>polyval</i> (x, c[, tensor])	Evaluate a polynomial at points x.
<i>polyval2d</i> (x, y, c)	Evaluate a 2-D polynomial at points (x, y).
<i>polyval3d</i> (x, y, z, c)	Evaluate a 3-D polynomial at points (x, y, z).
<i>polyvalnd</i> (pts, c)	Evaluate an N-D polynomial at points.
<i>polygrid2d</i> (x, y, c)	Evaluate a 2-D polynomial on the Cartesian product of x and y.
<i>polygrid3d</i> (x, y, z, c)	Evaluate a 3-D polynomial on the Cartesian product of x, y and z.

`polynomial.polynomial.polyadd(c1, c2)`

Add one polynomial to another.

Returns the sum of two polynomials $c1 + c2$. The arguments are sequences of coefficients from lowest order term to highest, i.e., `[1,2,3]` represents the polynomial $1 + 2*x + 3*x**2$.

Parameters

c1, c2

[array_like] 1-D arrays of polynomial coefficients ordered from low to high.

Returns**out**

[ndarray] The coefficient array representing their sum.

See also:*polysub, polymulx, polymul, polydiv, polypow***Examples**

```
>>> from numpy.polynomial import polynomial as P
>>> c1 = (1, 2, 3)
>>> c2 = (3, 2, 1)
>>> sum = P.polyadd(c1,c2); sum
array([4., 4., 4.])
>>> P.polyval(2, sum) # 4 + 4(2) + 4(2**2)
28.0
```

polynomial.polynomial.**polysub**(c1, c2)

Subtract one polynomial from another.

Returns the difference of two polynomials $c1 - c2$. The arguments are sequences of coefficients from lowest order term to highest, i.e., [1,2,3] represents the polynomial $1 + 2x + 3x^2$.

Parameters**c1, c2**

[array_like] 1-D arrays of polynomial coefficients ordered from low to high.

Returns**out**

[ndarray] Of coefficients representing their difference.

See also:*polyadd, polymulx, polymul, polydiv, polypow***Examples**

```
>>> from numpy.polynomial import polynomial as P
>>> c1 = (1, 2, 3)
>>> c2 = (3, 2, 1)
>>> P.polysub(c1,c2)
array([-2., 0., 2.])
>>> P.polysub(c2, c1) # -P.polysub(c1,c2)
array([ 2., 0., -2.])
```

polynomial.polynomial.**polymulx**(c)

Multiply a polynomial by x.

Multiply the polynomial c by x , where x is the independent variable.

Parameters

c
[array_like] 1-D array of polynomial coefficients ordered from low to high.

Returns

out
[ndarray] Array representing the result of the multiplication.

See also:

polyadd, polysub, polymul, polydiv, polypow

Examples

```
>>> from numpy.polynomial import polynomial as P
>>> c = (1, 2, 3)
>>> P.polymulx(c)
array([0., 1., 2., 3.])
```

`polynomial.polynomial.polymul(c1, c2)`

Multiply one polynomial by another.

Returns the product of two polynomials $c1 * c2$. The arguments are sequences of coefficients, from lowest order term to highest, e.g., [1,2,3] represents the polynomial $1 + 2*x + 3*x**2$.

Parameters

c1, c2
[array_like] 1-D arrays of coefficients representing a polynomial, relative to the “standard” basis, and ordered from lowest order term to highest.

Returns

out
[ndarray] Of the coefficients of their product.

See also:

polyadd, polysub, polymulx, polydiv, polypow

Examples

```
>>> from numpy.polynomial import polynomial as P
>>> c1 = (1, 2, 3)
>>> c2 = (3, 2, 1)
>>> P.polymul(c1, c2)
array([ 3.,  8., 14.,  8.,  3.])
```

`polynomial.polynomial.polydiv(c1, c2)`

Divide one polynomial by another.

Returns the quotient-with-remainder of two polynomials $c1 / c2$. The arguments are sequences of coefficients, from lowest order term to highest, e.g., [1,2,3] represents $1 + 2*x + 3*x**2$.

Parameters

c1, c2
[array_like] 1-D arrays of polynomial coefficients ordered from low to high.

Returns**[quo, rem]**

[ndarrays] Of coefficient series representing the quotient and remainder.

See also:*polyadd, polysub, polymulx, polymul, polypow***Examples**

```
>>> from numpy.polynomial import polynomial as P
>>> c1 = (1, 2, 3)
>>> c2 = (3, 2, 1)
>>> P.polydiv(c1, c2)
(array([3.]), array([-8., -4.]))
>>> P.polydiv(c2, c1)
(array([ 0.33333333]), array([ 2.66666667,  1.33333333])) # may vary
```

`polynomial.polynomial.polypow(c, pow, maxpower=None)`

Raise a polynomial to a power.

Returns the polynomial *c* raised to the power *pow*. The argument *c* is a sequence of coefficients ordered from low to high. i.e., [1,2,3] is the series $1 + 2*x + 3*x**2$.**Parameters****c**

[array_like] 1-D array of array of series coefficients ordered from low to high degree.

pow

[integer] Power to which the series will be raised

maxpower

[integer, optional] Maximum power allowed. This is mainly to limit growth of the series to unmanageable size. Default is 16

Returns**coef**

[ndarray] Power series of power.

See also:*polyadd, polysub, polymulx, polymul, polydiv***Examples**

```
>>> from numpy.polynomial import polynomial as P
>>> P.polypow([1, 2, 3], 2)
array([ 1.,  4., 10., 12.,  9.])
```

`polynomial.polynomial.polyval(x, c, tensor=True)`

Evaluate a polynomial at points x.

If *c* is of length *n* + 1, this function returns the value

$$p(x) = c_0 + c_1 * x + ... + c_n * x^n$$

The parameter x is converted to an array only if it is a tuple or a list, otherwise it is treated as a scalar. In either case, either x or its elements must support multiplication and addition both with themselves and with the elements of c .

If c is a 1-D array, then $p(x)$ will have the same shape as x . If c is multidimensional, then the shape of the result depends on the value of *tensor*. If *tensor* is true the shape will be $c.shape[1:] + x.shape$. If *tensor* is false the shape will be $c.shape[1:]$. Note that scalars have shape $()$.

Trailing zeros in the coefficients will be used in the evaluation, so they should be avoided if efficiency is a concern.

Parameters

x

[array_like, compatible object] If x is a list or tuple, it is converted to an ndarray, otherwise it is left unchanged and treated as a scalar. In either case, x or its elements must support addition and multiplication with themselves and with the elements of c .

c

[array_like] Array of coefficients ordered so that the coefficients for terms of degree n are contained in $c[n]$. If c is multidimensional the remaining indices enumerate multiple polynomials. In the two dimensional case the coefficients may be thought of as stored in the columns of c .

tensor

[boolean, optional] If True, the shape of the coefficient array is extended with ones on the right, one for each dimension of x . Scalars have dimension 0 for this action. The result is that every column of coefficients in c is evaluated for every element of x . If False, x is broadcast over the columns of c for the evaluation. This keyword is useful when c is multidimensional. The default value is True.

Returns

values

[ndarray, compatible object] The shape of the returned array is described above.

See also:

[*polyval2d*](#), [*polygrid2d*](#), [*polyval3d*](#), [*polygrid3d*](#)

Notes

The evaluation uses Horner's method.

When using coefficients from polynomials created with `Polynomial.fit()`, use `p(x)` or `polyval(x, p.convert().coef)` to handle domain/window scaling correctly, not `polyval(x, p.coef)`.

Examples

```
>>> import numpy as np
>>> from numpy.polynomial.polynomial import polyval
>>> polyval(1, [1,2,3])
6.0
>>> a = np.arange(4).reshape(2,2)
>>> a
array([[0, 1],
       [2, 3]])
>>> polyval(a, [1, 2, 3])
```

(continues on next page)

(continued from previous page)

```

array([[ 1.,   6.],
       [17.,  34.]])
>>> coef = np.arange(4).reshape(2, 2)  # multidimensional coefficients
>>> coef
array([[0, 1],
       [2, 3]])
>>> polyval([1, 2], coef, tensor=True)
array([[2.,   4.],
       [4.,   7.]])
>>> polyval([1, 2], coef, tensor=False)
array([2.,   7.])

```

`polynomial.polynomial.polyval2d(x, y, c)`

Evaluate a 2-D polynomial at points (x, y).

This function returns the value

$$p(x, y) = \sum_{i,j} c_{i,j} * x^i * y^j$$

The parameters x and y are converted to arrays only if they are tuples or a lists, otherwise they are treated as a scalars and they must have the same shape after conversion. In either case, either x and y or their elements must support multiplication and addition both with themselves and with the elements of c .

If c has fewer than two dimensions, ones are implicitly appended to its shape to make it 2-D. The shape of the result will be $c.shape[2:] + x.shape$.

Parameters

x, y

[array_like, compatible objects] The two dimensional series is evaluated at the points (x, y) , where x and y must have the same shape. If x or y is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and, if it isn't an ndarray, it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficient of the term of multi-degree i, j is contained in $c[i, j]$. If c has dimension greater than two the remaining indices enumerate multiple sets of coefficients.

Returns

values

[ndarray, compatible object] The values of the two dimensional polynomial at points formed with pairs of corresponding values from x and y .

See also:

[*polyval*](#), [*polygrid2d*](#), [*polyval3d*](#), [*polygrid3d*](#)

Examples

```
>>> from numpy.polynomial import polynomial as P
>>> c = ((1, 2, 3), (4, 5, 6))
>>> P.polyval2d(1, 1, c)
21.0
```

`polynomial.polynomial.polyval3d(x, y, z, c)`

Evaluate a 3-D polynomial at points (x, y, z).

This function returns the values:

$$p(x, y, z) = \sum_{i,j,k} c_{i,j,k} * x^i * y^j * z^k$$

The parameters x , y , and z are converted to arrays only if they are tuples or a lists, otherwise they are treated as a scalars and they must have the same shape after conversion. In either case, either x , y , and z or their elements must support multiplication and addition both with themselves and with the elements of c .

If c has fewer than 3 dimensions, ones are implicitly appended to its shape to make it 3-D. The shape of the result will be $c.shape[3:] + x.shape$.

Parameters

x, y, z

[array_like, compatible object] The three dimensional series is evaluated at the points (x, y, z) , where x , y , and z must have the same shape. If any of x , y , or z is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and if it isn't an ndarray it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficient of the term of multi-degree i,j,k is contained in $c[i, j, k]$. If c has dimension greater than 3 the remaining indices enumerate multiple sets of coefficients.

Returns

values

[ndarray, compatible object] The values of the multidimensional polynomial on points formed with triples of corresponding values from x , y , and z .

See also:

[*polyval*](#), [*polyval2d*](#), [*polygrid2d*](#), [*polygrid3d*](#)

Examples

```
>>> from numpy.polynomial import polynomial as P
>>> c = ((1, 2, 3), (4, 5, 6), (7, 8, 9))
>>> P.polyval3d(1, 1, 1, c)
45.0
```

`polynomial.polynomial.polyvalnd(pts, c)`

Evaluate an N-D polynomial at points.

This function returns the values:

$$p(pts, c) = \sum_{i_1, i_2, \dots, i_n} c_{i_1, i_2, \dots, i_n} * x_1^{i_1} * x_2^{i_2} \dots x_n^{i_n}$$

where $x_1, x_2, \dots, x_n = pts$. Note that pts may also be an (n, m) array.

The parameters in pts are converted to arrays only if they are tuples or lists, otherwise they are treated as scalars and they must have the same shape after conversion. In either case, either the elements of pts or their elements must support multiplication and addition both with themselves and with the elements of c .

If c has fewer than N dimensions, ones are implicitly appended to its shape to make it N -D. The shape of the result will be $c.shape[N:] + pts[0].shape$.

Parameters

pts

[tuple or list of array_like, compatible objects] The N -dimensional series is evaluated at the points $(x_1, x_2, \dots, x_n)$ provided in the pts iterable, where all elements must have the same shape. If any element is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and if it isn't an ndarray it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficient of the term of multi-degree $i, j, k, \dots$ is contained in $c[i, j, k, \dots]$. If c has dimension greater than N , the remaining indices enumerate multiple sets of coefficients.

Returns

values

[ndarray, compatible object] The values of the multidimensional polynomial on points formed with N -tuples of corresponding values from pts .

See also:

[*polyval*](#), [*polyval2d*](#), [*polyval3d*](#)

`polynomial.polynomial.polygrid2d(x, y, c)`

Evaluate a 2-D polynomial on the Cartesian product of x and y .

This function returns the values:

$$p(a, b) = \sum_{i,j} c_{i,j} * a^i * b^j$$

where the points (a, b) consist of all pairs formed by taking a from x and b from y . The resulting points form a grid with x in the first dimension and y in the second.

The parameters x and y are converted to arrays only if they are tuples or a lists, otherwise they are treated as scalars. In either case, either x and y or their elements must support multiplication and addition both with themselves and with the elements of c .

If c has fewer than two dimensions, ones are implicitly appended to its shape to make it 2-D. The shape of the result will be $c.shape[2:] + x.shape + y.shape$.

Parameters

x, y

[array_like, compatible objects] The two dimensional series is evaluated at the points in the Cartesian product of x and y . If x or y is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and, if it isn't an ndarray, it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficients for terms of degree i, j are contained in $c[i, j]$. If c has dimension greater than two the remaining indices enumerate multiple sets of coefficients.

Returns**values**

[ndarray, compatible object] The values of the two dimensional polynomial at points in the Cartesian product of x and y .

See also:

polyval, polyval2d, polyval3d, polygrid3d

Examples

```
>>> from numpy.polynomial import polynomial as P
>>> c = ((1, 2, 3), (4, 5, 6))
>>> P.polygrid2d([0, 1], [0, 1], c)
array([[ 1.,  6.],
       [ 5., 21.]])
```

`polynomial.polynomial.polygrid3d(x, y, z, c)`

Evaluate a 3-D polynomial on the Cartesian product of x , y and z .

This function returns the values:

$$p(a, b, c) = \sum_{i,j,k} c_{i,j,k} * a^i * b^j * c^k$$

where the points (a, b, c) consist of all triples formed by taking a from x , b from y , and c from z . The resulting points form a grid with x in the first dimension, y in the second, and z in the third.

The parameters x , y , and z are converted to arrays only if they are tuples or a lists, otherwise they are treated as a scalars. In either case, either x , y , and z or their elements must support multiplication and addition both with themselves and with the elements of c .

If c has fewer than three dimensions, ones are implicitly appended to its shape to make it 3-D. The shape of the result will be $c.shape[3:] + x.shape + y.shape + z.shape$.

Parameters **x, y, z**

[array_like, compatible objects] The three dimensional series is evaluated at the points in the Cartesian product of x , y , and z . If x , y , or z is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and, if it isn't an ndarray, it is treated as a scalar.

 c

[array_like] Array of coefficients ordered so that the coefficients for terms of degree i, j are contained in $c[i, j]$. If c has dimension greater than two the remaining indices enumerate multiple sets of coefficients.

Returns**values**

[ndarray, compatible object] The values of the two dimensional polynomial at points in the Cartesian product of x and y .

See also:

polyval, polyval2d, polygrid2d, polyval3d

Examples

```
>>> from numpy.polynomial import polynomial as P
>>> c = ((1, 2, 3), (4, 5, 6), (7, 8, 9))
>>> P.polygrid3d([0, 1], [0, 1], [0, 1], c)
array([[ 1., 13.],
       [ 6., 51.]])
```

Calculus

<code>polyder(c[, m, scl, axis])</code>	Differentiate a polynomial.
<code>polyint(c[, m, k, lbnd, scl, axis])</code>	Integrate a polynomial.

`polynomial.polynomial.polyder(c, m=1, scl=1, axis=0)`

Differentiate a polynomial.

Returns the polynomial coefficients *c* differentiated *m* times along *axis*. At each iteration the result is multiplied by *scl* (the scaling factor is for use in a linear change of variable). The argument *c* is an array of coefficients from low to high degree along each axis, e.g., [1,2,3] represents the polynomial $1 + 2x + 3x^2$ while [[1,2],[1,2]] represents $1 + 1x + 2y + 2xy$ if *axis*=0 is *x* and *axis*=1 is *y*.

Parameters

c

[array_like] Array of polynomial coefficients. If *c* is multidimensional the different axis correspond to different variables with the degree in each axis given by the corresponding index.

m

[int, optional] Number of derivatives taken, must be non-negative. (Default: 1)

scl

[scalar, optional] Each differentiation is multiplied by *scl*. The end result is multiplication by *scl**m*. This is for use in a linear change of variable. (Default: 1)

axis

[int, optional] Axis over which the derivative is taken. (Default: 0).

Returns

der

[ndarray] Polynomial coefficients of the derivative.

See also:

[`polyint`](#)

Examples

```
>>> from numpy.polynomial import polynomial as P
>>> c = (1, 2, 3, 4)
>>> P.polyder(c) # (d/dx)(c)
array([ 2.,  6., 12.])
>>> P.polyder(c, 3) # (d**3/dx**3)(c)
array([24.])
>>> P.polyder(c, scl=-1) # (d/d(-x))(c)
array([-2., -6., -12.])
>>> P.polyder(c, 2, -1) # (d**2/d(-x)**2)(c)
array([ 6., 24.])
```

`polynomial.polynomial.polyint(c, m=1, k=[], lbnd=0, scl=1, axis=0)`

Integrate a polynomial.

Returns the polynomial coefficients c integrated m times from $lbnd$ along $axis$. At each iteration the resulting series is **multiplied** by scl and an integration constant, k , is added. The scaling factor is for use in a linear change of variable. (“Buyer beware”: note that, depending on what one is doing, one may want scl to be the reciprocal of what one might expect; for more information, see the Notes section below.) The argument c is an array of coefficients, from low to high degree along each axis, e.g., $[1,2,3]$ represents the polynomial $1 + 2x + 3x^2$ while $[[1,2],[1,2]]$ represents $1 + 1x + 2y + 2xy$ if $axis=0$ is x and $axis=1$ is y .

Parameters

- c**
[array_like] 1-D array of polynomial coefficients, ordered from low to high.
- m**
[int, optional] Order of integration, must be positive. (Default: 1)
- k**
[[], list, scalar], optional] Integration constant(s). The value of the first integral at zero is the first value in the list, the value of the second integral at zero is the second value, etc. If $k == []$ (the default), all constants are set to zero. If $m == 1$, a single scalar can be given instead of a list.
- lbnd**
[scalar, optional] The lower bound of the integral. (Default: 0)
- scl**
[scalar, optional] Following each integration the result is *multiplied* by scl before the integration constant is added. (Default: 1)
- axis**
[int, optional] Axis over which the integral is taken. (Default: 0).

Returns

- S**
[ndarray] Coefficient array of the integral.

Raises

ValueError

If $m < 1$, $\text{len}(k) > m$, $\text{np.ndim}(lbnd) \neq 0$, or $\text{np.ndim}(scl) \neq 0$.

See also:

[`polyder`](#)

Notes

Note that the result of each integration is *multiplied* by *scl*. Why is this important to note? Say one is making a linear change of variable $u = ax + b$ in an integral relative to x . Then $dx = du/a$, so one will need to set *scl* equal to $1/a$ - perhaps not what one would have first thought.

Examples

```
>>> from numpy.polynomial import polynomial as P
>>> c = (1, 2, 3)
>>> P.polyint(c) # should return array([0, 1, 1, 1])
array([0., 1., 1., 1.])
>>> P.polyint(c, 3) # should return array([0, 0, 0, 1/6, 1/12, 1/20])
array([ 0., 0., 0., 0.16666667, 0.08333333, # may
↪ vary
      0.05      ])
>>> P.polyint(c, k=3) # should return array([3, 1, 1, 1])
array([3., 1., 1., 1.])
>>> P.polyint(c, lbnd=-2) # should return array([6, 1, 1, 1])
array([6., 1., 1., 1.])
>>> P.polyint(c, scl=-2) # should return array([0, -2, -2, -2])
array([ 0., -2., -2., -2.])
```

Misc Functions

<code>polyfromroots</code> (roots)	Generate a monic polynomial with given roots.
<code>polyroots</code> (c)	Compute the roots of a polynomial.
<code>polyvalfromroots</code> (x, r[, tensor])	Evaluate a polynomial specified by its roots at points x.
<code>polyvander</code> (x, deg)	Vandermonde matrix of given degree.
<code>polyvander2d</code> (x, y, deg)	Pseudo-Vandermonde matrix of given degrees.
<code>polyvander3d</code> (x, y, z, deg)	Pseudo-Vandermonde matrix of given degrees.
<code>polycompanion</code> (c)	Return the companion matrix of c.
<code>polyfit</code> (x, y, deg[, rcond, full, w])	Least-squares fit of a polynomial to data.
<code>polytrim</code> (c[, tol])	Remove "small" "trailing" coefficients from a polynomial.
<code>polyline</code> (off, scl)	Returns an array representing a linear polynomial.

`polynomial.polynomial.polyfromroots`(roots)

Generate a monic polynomial with given roots.

Return the coefficients of the polynomial

$$p(x) = (x - r_0) * (x - r_1) * \dots * (x - r_n),$$

where the r_n are the roots specified in *roots*. If a zero has multiplicity n , then it must appear in *roots* n times. For instance, if 2 is a root of multiplicity three and 3 is a root of multiplicity 2, then *roots* looks something like [2, 2, 2, 3, 3]. The roots can appear in any order.

If the returned coefficients are *c*, then

$$p(x) = c_0 + c_1 * x + \dots + x^n$$

The coefficient of the last term is 1 for monic polynomials in this form.

Parameters**roots**

[array_like] Sequence containing the roots.

Returns**out**

[ndarray] 1-D array of the polynomial's coefficients. If all the roots are real, then *out* is also real, otherwise it is complex. (see Examples below).

See also:

```
numpy.polynomial.chebyshev.chebfromroots
numpy.polynomial.legendre.legfromroots
numpy.polynomial.laguerre.lagfromroots
numpy.polynomial.hermite.hermfromroots
numpy.polynomial.hermite_e.hermefromroots
```

Notes

The coefficients are determined by multiplying together linear factors of the form $(x - r_i)$, i.e.

$$p(x) = (x - r_0)(x - r_1) \dots (x - r_n)$$

where $n == \text{len}(\text{roots}) - 1$; note that this implies that 1 is always returned for a_n .

Examples

```
>>> from numpy.polynomial import polynomial as P
>>> P.polyfromroots((-1,0,1)) # x(x - 1)(x + 1) = x^3 - x
array([ 0., -1.,  0.,  1.])
>>> j = complex(0,1)
>>> P.polyfromroots((-j,j)) # complex returned, though values are real
array([1.+0.j,  0.+0.j,  1.+0.j])
```

`polynomial.polynomial.polyroots(c)`

Compute the roots of a polynomial.

Return the roots (a.k.a. “zeros”) of the polynomial

$$p(x) = \sum_i c[i] * x^i.$$

Parameters**c**

[1-D array_like] 1-D array of polynomial coefficients.

Returns**out**

[ndarray] Array of the roots of the polynomial. If all the roots are real, then *out* is also real, otherwise it is complex.

See also:

```

numpy.polynomial.chebyshev.chebroots
numpy.polynomial.legendre.legroots
numpy.polynomial.laguerre.lagrooots
numpy.polynomial.hermite.hermroots
numpy.polynomial.hermite_e.hermroots

```

Notes

The root estimates are obtained as the eigenvalues of the companion matrix, Roots far from the origin of the complex plane may have large errors due to the numerical instability of the power series for such values. Roots with multiplicity greater than 1 will also show larger errors as the value of the series near such points is relatively insensitive to errors in the roots. Isolated roots near the origin can be improved by a few iterations of Newton's method.

Examples

```

>>> import numpy.polynomial.polynomial as poly
>>> poly.polyroots(poly.polyfromroots((-1, 0, 1)))
array([-1.,  0.,  1.])
>>> poly.polyroots(poly.polyfromroots((-1, 0, 1))).dtype
dtype('float64')
>>> j = complex(0, 1)
>>> poly.polyroots(poly.polyfromroots((-j, 0, j)))
array([ 0.00000000e+00+0.j,  0.00000000e+00+1.j,  2.77555756e-17-1.j]) # may_
↪ vary

```

`polynomial.polynomial.polyvalfromroots` (*x*, *r*, *tensor=True*)

Evaluate a polynomial specified by its roots at points *x*.

If *r* is of length *N*, this function returns the value

$$p(x) = \prod_{n=1}^N (x - r_n)$$

The parameter *x* is converted to an array only if it is a tuple or a list, otherwise it is treated as a scalar. In either case, either *x* or its elements must support multiplication and addition both with themselves and with the elements of *r*.

If *r* is a 1-D array, then `p(x)` will have the same shape as *x*. If *r* is multidimensional, then the shape of the result depends on the value of *tensor*. If *tensor* is `True` the shape will be `r.shape[1:] + x.shape`; that is, each polynomial is evaluated at every value of *x*. If *tensor* is `False`, the shape will be `r.shape[1:]`; that is, each polynomial is evaluated only for the corresponding broadcast value of *x*. Note that scalars have shape `(,)`.

Parameters

x

[array_like, compatible object] If *x* is a list or tuple, it is converted to an ndarray, otherwise it is left unchanged and treated as a scalar. In either case, *x* or its elements must support addition and multiplication with themselves and with the elements of *r*.

r

[array_like] Array of roots. If *r* is multidimensional the first index is the root index, while the remaining indices enumerate multiple polynomials. For instance, in the two dimensional case the roots of each polynomial may be thought of as stored in the columns of *r*.

tensor

[boolean, optional] If True, the shape of the roots array is extended with ones on the right, one for each dimension of x . Scalars have dimension 0 for this action. The result is that every column of coefficients in r is evaluated for every element of x . If False, x is broadcast over the columns of r for the evaluation. This keyword is useful when r is multidimensional. The default value is True.

Returns**values**

[ndarray, compatible object] The shape of the returned array is described above.

See also:

[*polyroots*](#), [*polyfromroots*](#), [*polyval*](#)

Examples

```
>>> from numpy.polynomial.polynomial import polyvalfromroots
>>> polyvalfromroots(1, [1, 2, 3])
0.0
>>> a = np.arange(4).reshape(2, 2)
>>> a
array([[0, 1],
       [2, 3]])
>>> polyvalfromroots(a, [-1, 0, 1])
array([[ -0.,   0.],
       [ 6.,  24.]])
>>> r = np.arange(-2, 2).reshape(2,2) # multidimensional coefficients
>>> r # each column of r defines one polynomial
array([[ -2,  -1],
       [ 0,   1]])
>>> b = [-2, 1]
>>> polyvalfromroots(b, r, tensor=True)
array([[ -0.,   3.],
       [ 3.,   0.]])
>>> polyvalfromroots(b, r, tensor=False)
array([ -0.,   0.]])
```

`polynomial.polynomial.polyvander` (x , deg)

Vandermonde matrix of given degree.

Returns the Vandermonde matrix of degree deg and sample points x . The Vandermonde matrix is defined by

$$V[... , i] = x^i,$$

where $0 \leq i \leq deg$. The leading indices of V index the elements of x and the last index is the power of x .

If c is a 1-D array of coefficients of length $n + 1$ and V is the matrix $V = \text{polyvander}(x, n)$, then $\text{np.dot}(V, c)$ and $\text{polyval}(x, c)$ are the same up to roundoff. This equivalence is useful both for least squares fitting and for the evaluation of a large number of polynomials of the same degree and sample points.

Parameters**x**

[array_like] Array of points. The dtype is converted to float64 or complex128 depending on whether any of the elements are complex. If x is scalar it is converted to a 1-D array.

deg

[int] Degree of the resulting matrix.

Returns**vander**[ndarray.] The Vandermonde matrix. The shape of the returned matrix is `x.shape + (deg + 1,)`, where the last index is the power of x . The dtype will be the same as the converted x .**See also:***[polyvander2d](#)*, *[polyvander3d](#)***Examples**

The Vandermonde matrix of degree `deg = 5` and sample points `x = [-1, 2, 3]` contains the element-wise powers of x from 0 to 5 as its columns.

```
>>> from numpy.polynomial import polynomial as P
>>> x, deg = [-1, 2, 3], 5
>>> P.polyvander(x=x, deg=deg)
array([[ 1., -1., 1., -1., 1., -1.],
       [ 1., 2., 4., 8., 16., 32.],
       [ 1., 3., 9., 27., 81., 243.]])
```

`polynomial.polynomial.polyvander2d(x, y, deg)`

Pseudo-Vandermonde matrix of given degrees.

Returns the pseudo-Vandermonde matrix of degrees `deg` and sample points `(x, y)`. The pseudo-Vandermonde matrix is defined by

$$V[...,(deg[1] + 1) * i + j] = x^i * y^j,$$

where $0 \leq i \leq deg[0]$ and $0 \leq j \leq deg[1]$. The leading indices of V index the points `(x, y)` and the last index encodes the powers of x and y .

If `V = polyvander2d(x, y, [xdeg, ydeg])`, then the columns of V correspond to the elements of a 2-D coefficient array `c` of shape `(xdeg + 1, ydeg + 1)` in the order

$$c_{00}, c_{01}, c_{02}, \dots, c_{10}, c_{11}, c_{12}, \dots$$

and `np.dot(V, c.flat)` and `polyval2d(x, y, c)` will be the same up to roundoff. This equivalence is useful both for least squares fitting and for the evaluation of a large number of 2-D polynomials of the same degrees and sample points.

Parameters**x, y**

[array_like] Arrays of point coordinates, all of the same shape. The dtypes will be converted to either float64 or complex128 depending on whether any of the elements are complex. Scalars are converted to 1-D arrays.

deg[list of ints] List of maximum degrees of the form `[x_deg, y_deg]`.**Returns****vander2d**

[ndarray] The shape of the returned matrix is `x.shape + (order,)`, where `order = (deg[0] + 1) * (deg[1] + 1)`. The dtype will be the same as the converted x and y .

See also:

polyvander, *polyvander3d*, *polyval2d*, *polyval3d*

Examples

```
>>> import numpy as np
```

The 2-D pseudo-Vandermonde matrix of degree `[1, 2]` and sample points `x = [-1, 2]` and `y = [1, 3]` is as follows:

```
>>> from numpy.polynomial import polynomial as P
>>> x = np.array([-1, 2])
>>> y = np.array([1, 3])
>>> m, n = 1, 2
>>> deg = np.array([m, n])
>>> V = P.polyvander2d(x=x, y=y, deg=deg)
>>> V
array([[ 1.,  1.,  1., -1., -1., -1.],
       [ 1.,  3.,  9.,  2.,  6., 18.]])
```

We can verify the columns for any $0 \leq i \leq m$ and $0 \leq j \leq n$:

```
>>> i, j = 0, 1
>>> V[:, (deg[1]+1)*i + j] == x**i * y**j
array([ True,  True])
```

The (1D) Vandermonde matrix of sample points `x` and degree `m` is a special case of the (2D) pseudo-Vandermonde matrix with `y` points all zero and degree `[m, 0]`.

```
>>> P.polyvander2d(x=x, y=0*x, deg=(m, 0)) == P.polyvander(x=x, deg=m)
array([[ True,  True],
       [ True,  True]])
```

`polynomial.polynomial.polyvander3d(x, y, z, deg)`

Pseudo-Vandermonde matrix of given degrees.

Returns the pseudo-Vandermonde matrix of degrees `deg` and sample points `(x, y, z)`. If `l, m, n` are the given degrees in `x, y, z`, then The pseudo-Vandermonde matrix is defined by

$$V[...,(m+1)(n+1)i + (n+1)j + k] = x^i * y^j * z^k,$$

where $0 \leq i \leq l, 0 \leq j \leq m$, and $0 \leq k \leq n$. The leading indices of `V` index the points `(x, y, z)` and the last index encodes the powers of `x, y`, and `z`.

If `V = polyvander3d(x, y, z, [xdeg, ydeg, zdeg])`, then the columns of `V` correspond to the elements of a 3-D coefficient array `c` of shape `(xdeg + 1, ydeg + 1, zdeg + 1)` in the order

$$c_{000}, c_{001}, c_{002}, \dots, c_{010}, c_{011}, c_{012}, \dots$$

and `np.dot(V, c.flat)` and `polyval3d(x, y, z, c)` will be the same up to roundoff. This equivalence is useful both for least squares fitting and for the evaluation of a large number of 3-D polynomials of the same degrees and sample points.

Parameters

x, y, z

[array_like] Arrays of point coordinates, all of the same shape. The dtypes will be converted to either float64 or complex128 depending on whether any of the elements are complex. Scalars are converted to 1-D arrays.

deg

[list of ints] List of maximum degrees of the form [x_deg, y_deg, z_deg].

Returns**vander3d**

[ndarray] The shape of the returned matrix is `x.shape + (order,)`, where `order = (deg[0] + 1) * (deg[1] + 1) * (deg[2] + 1)`. The dtype will be the same as the converted x, y, and z.

[polyvander](#), *[polyvander3d](#)*, *[polyval2d](#)*, *[polyval3d](#)*

Examples

```
>>> import numpy as np
>>> from numpy.polynomial import polynomial as P
>>> x = np.asarray([-1, 2, 1])
>>> y = np.asarray([1, -2, -3])
>>> z = np.asarray([2, 2, 5])
>>> l, m, n = [2, 2, 1]
>>> deg = [l, m, n]
>>> V = P.polyvander3d(x=x, y=y, z=z, deg=deg)
>>> V
array([[ 1.,  2.,  1.,  2.,  1.,  2., -1., -2., -1.,
        -2., -1., -2.,  1.,  2.,  1.,  2.,  1.,  2.],
       [ 1.,  2., -2., -4.,  4.,  8.,  2.,  4., -4.,
        -8.,  8., 16.,  4.,  8., -8., -16., 16., 32.],
       [ 1.,  5., -3., -15.,  9., 45.,  1.,  5., -3.,
       -15.,  9., 45.,  1.,  5., -3., -15.,  9., 45.]])
```

We can verify the columns for any $0 \leq i \leq l, 0 \leq j \leq m$, and $0 \leq k \leq n$

```
>>> i, j, k = 2, 1, 0
>>> V[:, (m+1)*(n+1)*i + (n+1)*j + k] == x**i * y**j * z**k
array([ True,  True,  True])
```

`polynomial.polynomial.polycompanion(c)`

Return the companion matrix of c.

The companion matrix for power series cannot be made symmetric by scaling the basis, so this function differs from those for the orthogonal polynomials.

Parameters**c**

[array_like] 1-D array of polynomial coefficients ordered from low to high degree.

Returns**mat**

[ndarray] Companion matrix of dimensions (deg, deg).

Examples

```
>>> from numpy.polynomial import polynomial as P
>>> c = (1, 2, 3)
>>> P.polycompanion(c)
array([[ 0.          , -0.33333333],
       [ 1.          , -0.66666667]])
```

`polynomial.polynomial.polyfit(x, y, deg, rcond=None, full=False, w=None)`

Least-squares fit of a polynomial to data.

Return the coefficients of a polynomial of degree *deg* that is the least squares fit to the data values *y* given at points *x*. If *y* is 1-D the returned coefficients will also be 1-D. If *y* is 2-D multiple fits are done, one for each column of *y*, and the resulting coefficients are stored in the corresponding columns of a 2-D return. The fitted polynomial(s) are in the form

$$p(x) = c_0 + c_1 * x + \dots + c_n * x^n,$$

where *n* is *deg*.

Parameters

- x**
[array_like, shape (*M*,)] x-coordinates of the *M* sample (data) points (*x*[*i*], *y*[*i*]).
- y**
[array_like, shape (*M*,) or (*M*, *K*)] y-coordinates of the sample points. Several sets of sample points sharing the same x-coordinates can be (independently) fit with one call to `polyfit` by passing in for *y* a 2-D array that contains one data set per column.
- deg**
[int or 1-D array_like] Degree(s) of the fitting polynomials. If *deg* is a single integer all terms up to and including the *deg*'th term are included in the fit. For NumPy versions $\geq 1.11.0$ a list of integers specifying the degrees of the terms to include may be used instead.
- rcond**
[float, optional] Relative condition number of the fit. Singular values smaller than *rcond*, relative to the largest singular value, will be ignored. The default value is `len(x) * eps`, where *eps* is the relative precision of the platform's float type, about 2e-16 in most cases.
- full**
[bool, optional] Switch determining the nature of the return value. When `False` (the default) just the coefficients are returned; when `True`, diagnostic information from the singular value decomposition (used to solve the fit's matrix equation) is also returned.
- w**
[array_like, shape (*M*,), optional] Weights. If not `None`, the weight *w*[*i*] applies to the unsquared residual *y*[*i*] - *y*_hat[*i*] at *x*[*i*]. Ideally the weights are chosen so that the errors of the products *w*[*i*] * *y*[*i*] all have the same variance. When using inverse-variance weighting, use *w*[*i*] = `1/sigma(y[i])`. The default value is `None`.

Returns

- coef**
[ndarray, shape (*deg* + 1,) or (*deg* + 1, *K*)] Polynomial coefficients ordered from low to high. If *y* was 2-D, the coefficients in column *k* of *coef* represent the polynomial fit to the data in *y*'s *k*-th column.
- [residuals, rank, singular_values, rcond]**
[list] These values are only returned if `full == True`

- residuals – sum of squared residuals of the least squares fit
- rank – the numerical rank of the scaled Vandermonde matrix
- singular_values – singular values of the scaled Vandermonde matrix
- rcond – value of *rcond*.

For more details, see `numpy.linalg.lstsq`.

Raises

RankWarning

Raised if the matrix in the least-squares fit is rank deficient. The warning is only raised if `full == False`. The warnings can be turned off by:

```
>>> import warnings
>>> warnings.simplefilter('ignore', np.exceptions.RankWarning)
```

`numpy.polynomial.chebyshev.chebfit`
`numpy.polynomial.legendre.legfit`
`numpy.polynomial.laguerre.lagfit`
`numpy.polynomial.hermite.hermfit`
`numpy.polynomial.hermite_e.hermefit`
`polyval`

Evaluates a polynomial.

`polyvander`

Vandermonde matrix for powers.

`numpy.linalg.lstsq`

Computes a least-squares fit from the matrix.

`scipy.interpolate.UnivariateSpline`

Computes spline fits.

Notes

The solution is the coefficients of the polynomial p that minimizes the sum of the weighted squared errors

$$E = \sum_j w_j^2 * |y_j - p(x_j)|^2,$$

where the w_j are the weights. This problem is solved by setting up the (typically) over-determined matrix equation:

$$V(x) * c = w * y,$$

where V is the weighted pseudo Vandermonde matrix of x , c are the coefficients to be solved for, w are the weights, and y are the observed values. This equation is then solved using the singular value decomposition of V .

If some of the singular values of V are so small that they are neglected (and `full == False`), a `RankWarning` will be raised. This means that the coefficient values may be poorly determined. Fitting to a lower order polynomial will usually get rid of the warning (but may not be what you want, of course; if you have independent reason(s) for choosing the degree which isn't working, you may have to: a) reconsider those reasons, and/or b) reconsider the quality of your data). The `rcond` parameter can also be set to a value smaller than its default, but the resulting fit may be spurious and have large contributions from roundoff error.

Polynomial fits using double precision tend to “fail” at about (polynomial) degree 20. Fits using Chebyshev or Legendre series are generally better conditioned, but much can still depend on the distribution of the sample points and the smoothness of the data. If the quality of the fit is inadequate, splines may be a good alternative.

Examples

```
>>> import numpy as np
>>> from numpy.polynomial import polynomial as P
>>> x = np.linspace(-1,1,51) # x "data": [-1, -0.96, ..., 0.96, 1]
>>> rng = np.random.default_rng()
>>> err = rng.normal(size=len(x))
>>> y = x**3 - x + err # x^3 - x + Gaussian noise
>>> c, stats = P.polyfit(x,y,3,full=True)
>>> c # c[0], c[1] approx. -1, c[2] should be approx. 0, c[3] approx. 1
array([ 0.23111996, -1.02785049, -0.2241444 ,  1.08405657]) # may vary
>>> stats # note the large SSR, explaining the rather poor results
[array([48.312088]), # may vary
 4,
 array([1.38446749, 1.32119158, 0.50443316, 0.28853036]),
 1.1324274851176597e-14]
```

Same thing without the added noise

```
>>> y = x**3 - x
>>> c, stats = P.polyfit(x,y,3,full=True)
>>> c # c[0], c[1] ~= -1, c[2] should be "very close to 0", c[3] ~= 1
array([-6.73496154e-17, -1.00000000e+00,  0.00000000e+00,  1.00000000e+00])
>>> stats # note the minuscule SSR
[array([8.79579319e-31]),
 np.int32(4),
 array([1.38446749, 1.32119158, 0.50443316, 0.28853036]),
 1.1324274851176597e-14]
```

`polynomial.polynomial.polytrim(c, tol=0)`

Remove “small” “trailing” coefficients from a polynomial.

“Small” means “small in absolute value” and is controlled by the parameter *tol*; “trailing” means highest order coefficient(s), e.g., in $[0, 1, 1, 0, 0]$ (which represents $0 + x + x^2 + 0x^3 + 0x^4$) both the 3-rd and 4-th order coefficients would be “trimmed.”

Parameters

c

[array_like] 1-d array of coefficients, ordered from lowest order to highest.

tol

[number, optional] Trailing (i.e., highest order) elements with absolute value less than or equal to *tol* (default value is zero) are removed.

Returns

trimmed

[ndarray] 1-d array with trailing zeros removed. If the resulting series would be empty, a series containing a single zero is returned.

Raises

ValueError

If *tol* < 0

Examples

```
>>> from numpy.polynomial import polyutils as pu
>>> pu.trimcoef((0,0,3,0,5,0,0))
array([0., 0., 3., 0., 5.])
>>> pu.trimcoef((0,0,1e-3,0,1e-5,0,0),1e-3) # item == tol is trimmed
array([0.])
>>> i = complex(0,1) # works for complex
>>> pu.trimcoef((3e-4,1e-3*(1-i),5e-4,2e-5*(1+i)), 1e-3)
array([0.0003+0.j      , 0.001 -0.001j])
```

`polynomial.polynomial.polyline` (*off*, *scl*)

Returns an array representing a linear polynomial.

Parameters

off, scl

[scalars] The “y-intercept” and “slope” of the line, respectively.

Returns

y

[ndarray] This module’s representation of the linear polynomial $\text{off} + \text{scl} \cdot x$.

`numpy.polynomial.legendre.legline`
`numpy.polynomial.laguerre.lagline`
`numpy.polynomial.hermite.hermline`
`numpy.polynomial.hermite_e.hermeline`

Examples

```
>>> from numpy.polynomial import polynomial as P
>>> P.polyline(1, -1)
array([ 1, -1])
>>> P.polyval(1, P.polyline(1, -1)) # should be 0
0.0
```

`numpy.polynomial`

Chebyshev Series (`numpy.polynomial.chebyshev`)

This module provides a number of objects (mostly functions) useful for dealing with Chebyshev series, including a `Chebyshev` class that encapsulates the usual arithmetic operations. (General information on how this module represents and works with such polynomials is in the docstring for its “parent” sub-package, `numpy.polynomial`).

Classes

<code>Chebyshev</code> (coef[, domain, window, symbol])	A Chebyshev series class.
---	---------------------------

class `numpy.polynomial.chebyshev.Chebyshev` (coef, domain=None, window=None, symbol='x')

A Chebyshev series class.

The Chebyshev class provides the standard Python numerical methods '+', '-', '*', '//', '%', 'divmod', '**', and '()' as well as the attributes and methods listed below.

Parameters

coef

[array_like] Chebyshev coefficients in order of increasing degree, i.e., (1, 2, 3) gives $1 * T_0(x) + 2 * T_1(x) + 3 * T_2(x)$.

domain

[(2,) array_like, optional] Domain to use. The interval [domain[0], domain[1]] is mapped to the interval [window[0], window[1]] by shifting and scaling. The default value is [-1., 1.].

window

[(2,) array_like, optional] Window, see domain for its use. The default value is [-1., 1.].

symbol

[str, optional] Symbol used to represent the independent variable in string representations of the polynomial expression, e.g. for printing. The symbol must be a valid Python identifier. Default value is 'x'.

New in version 1.24.

Attributes

symbol

Methods

<code>__call__(arg)</code>	Call self as a function.
<code>basis(deg[, domain, window, symbol])</code>	Series basis polynomial of degree <i>deg</i> .
<code>cast(series[, domain, window])</code>	Convert series to series of this class.
<code>convert([domain, kind, window])</code>	Convert series to a different kind and/or domain and/or window.
<code>copy()</code>	Return a copy.
<code>cutdeg(deg)</code>	Truncate series to the given degree.
<code>degree()</code>	The degree of the series.
<code>deriv([m])</code>	Differentiate.
<code>fit(x, y, deg[, domain, rcond, full, w, ...])</code>	Least squares fit to data.
<code>fromroots(roots[, domain, window, symbol])</code>	Return series instance that has the specified roots.
<code>has_samecoef(other)</code>	Check if coefficients match.
<code>has_samedomain(other)</code>	Check if domains match.
<code>has_sametype(other)</code>	Check if types match.
<code>has_samewindow(other)</code>	Check if windows match.
<code>identity([domain, window, symbol])</code>	Identity function.
<code>integ([m, k, lbnd])</code>	Integrate.
<code>interpolate(func, deg[, domain, args])</code>	Interpolate a function at the Chebyshev points of the first kind.
<code>linspace([n, domain])</code>	Return x, y values at equally spaced points in domain.
<code>mapparms()</code>	Return the mapping parameters.
<code>roots()</code>	Return the roots of the series polynomial.
<code>trim([tol])</code>	Remove trailing coefficients
<code>truncate(size)</code>	Truncate series to length <i>size</i> .

method

`polynomial.chebyshev.Chebyshev.__call__(arg)`

Call self as a function.

method

classmethod `polynomial.chebyshev.Chebyshev.basis(deg, domain=None, window=None, symbol='x')`

Series basis polynomial of degree *deg*.

Returns the series representing the basis polynomial of degree *deg*.

Parameters

deg

[int] Degree of the basis polynomial for the series. Must be ≥ 0 .

domain

[[None, array_like], optional] If given, the array must be of the form `[beg, end]`, where *beg* and *end* are the endpoints of the domain. If None is given then the class domain is used. The default is None.

window

[[None, array_like], optional] If given, the resulting array must be if the form `[beg, end]`, where *beg* and *end* are the endpoints of the window. If None is given then the class window is used. The default is None.

symbol

[str, optional] Symbol representing the independent variable. Default is 'x'.

Returns**new_series**

[series] A series with the coefficient of the *deg* term set to one and all others zero.

method

classmethod `polynomial.chebyshev.Chebyshev.cast` (*series*, *domain=None*, *window=None*)

Convert series to series of this class.

The *series* is expected to be an instance of some polynomial series of one of the types supported by the `numpy.polynomial` module, but could be some other class that supports the `convert` method.

Parameters**series**

[series] The series instance to be converted.

domain

[[None, array_like], optional] If given, the array must be of the form `[beg, end]`, where `beg` and `end` are the endpoints of the domain. If None is given then the class domain is used. The default is None.

window

[[None, array_like], optional] If given, the resulting array must be of the form `[beg, end]`, where `beg` and `end` are the endpoints of the window. If None is given then the class window is used. The default is None.

Returns**new_series**

[series] A series of the same kind as the calling class and equal to *series* when evaluated.

See also:

[*convert*](#)

similar instance method

method

`polynomial.chebyshev.Chebyshev.convert` (*domain=None*, *kind=None*, *window=None*)

Convert series to a different kind and/or domain and/or window.

Parameters**domain**

[array_like, optional] The domain of the converted series. If the value is None, the default domain of *kind* is used.

kind

[class, optional] The polynomial series type class to which the current instance should be converted. If *kind* is None, then the class of the current instance is used.

window

[array_like, optional] The window of the converted series. If the value is None, the default window of *kind* is used.

Returns**new_series**

[series] The returned class can be of different type than the current instance and/or have a different domain and/or different window.

Notes

Conversion between domains and class types can result in numerically ill defined series.

method

```
polynomial.chebyshev.Chebyshev.copy()
```

Return a copy.

Returns

new_series

[series] Copy of self.

method

```
polynomial.chebyshev.Chebyshev.cutdeg(deg)
```

Truncate series to the given degree.

Reduce the degree of the series to *deg* by discarding the high order terms. If *deg* is greater than the current degree a copy of the current series is returned. This can be useful in least squares where the coefficients of the high degree terms may be very small.

Parameters

deg

[non-negative int] The series is reduced to degree *deg* by discarding the high order terms. The value of *deg* must be a non-negative integer.

Returns

new_series

[series] New instance of series with reduced degree.

method

```
polynomial.chebyshev.Chebyshev.degree()
```

The degree of the series.

Returns

degree

[int] Degree of the series, one less than the number of coefficients.

Examples

Create a polynomial object for $1 + 7x + 4x^2$:

```
>>> np.polynomial.set_default_printstyle("unicode")
>>> poly = np.polynomial.Polynomial([1, 7, 4])
>>> print(poly)
1.0 + 7.0·x + 4.0·x2
>>> poly.degree()
2
```

Note that this method does not check for non-zero coefficients. You must trim the polynomial to remove any trailing zeroes:

```

>>> poly = np.polynomial.Polynomial([1, 7, 0])
>>> print(poly)
1.0 + 7.0·x + 0.0·x2
>>> poly.degree()
2
>>> poly.trim().degree()
1

```

method

`polynomial.chebyshev.Chebyshev.deriv(m=1)`

Differentiate.

Return a series instance of that is the derivative of the current series.

Parameters

m

[non-negative int] Find the derivative of order *m*.

Returns

new_series

[series] A new series representing the derivative. The domain is the same as the domain of the differentiated series.

method

classmethod `polynomial.chebyshev.Chebyshev.fit(x, y, deg, domain=None, rcond=None, full=False, w=None, window=None, symbol='x')`

Least squares fit to data.

Return a series instance that is the least squares fit to the data *y* sampled at *x*. The domain of the returned instance can be specified and this will often result in a superior fit with less chance of ill conditioning.

Parameters

x

[array_like, shape (M,)] x-coordinates of the M sample points (*x*[*i*], *y*[*i*]).

y

[array_like, shape (M,)] y-coordinates of the M sample points (*x*[*i*], *y*[*i*]).

deg

[int or 1-D array_like] Degree(s) of the fitting polynomials. If *deg* is a single integer all terms up to and including the *deg*'th term are included in the fit. For NumPy versions $\geq 1.11.0$ a list of integers specifying the degrees of the terms to include may be used instead.

domain

[{None, [beg, end], []}, optional] Domain to use for the returned series. If *None*, then a minimal domain that covers the points *x* is chosen. If [] the class domain is used. The default value was the class domain in NumPy 1.4 and *None* in later versions. The [] option was added in numpy 1.5.0.

rcond

[float, optional] Relative condition number of the fit. Singular values smaller than this relative to the largest singular value will be ignored. The default value is `len(x)*eps`, where *eps* is the relative precision of the float type, about 2e-16 in most cases.

full

[bool, optional] Switch determining nature of return value. When it is False (the default) just the coefficients are returned, when True diagnostic information from the singular value decomposition is also returned.

w

[array_like, shape (M,), optional] Weights. If not None, the weight $w[i]$ applies to the unsquared residual $y[i] - \hat{y}[i]$ at $x[i]$. Ideally the weights are chosen so that the errors of the products $w[i] * y[i]$ all have the same variance. When using inverse-variance weighting, use $w[i] = 1/\text{sigma}(y[i])$. The default value is None.

window

[[[beg, end]], optional] Window to use for the returned series. The default value is the default class domain

symbol

[str, optional] Symbol representing the independent variable. Default is 'x'.

Returns**new_series**

[series] A series that represents the least squares fit to the data and has the domain and window specified in the call. If the coefficients for the unscaled and unshifted basis polynomials are of interest, do `new_series.convert().coef`.

[resid, rank, sv, rcond]

[list] These values are only returned if `full == True`

- resid – sum of squared residuals of the least squares fit
- rank – the numerical rank of the scaled Vandermonde matrix
- sv – singular values of the scaled Vandermonde matrix
- rcond – value of *rcond*.

For more details, see [*linalg.lstsq*](#).

method

classmethod `polynomial.chebyshev.Chebyshev.fromroots` (*roots*, *domain*=[],
window=None, *symbol*='x')

Return series instance that has the specified roots.

Returns a series representing the product $(x - r[0]) * (x - r[1]) * \dots * (x - r[n-1])$, where *r* is a list of roots.

Parameters**roots**

[array_like] List of roots.

domain

[[[], None, array_like], optional] Domain for the resulting series. If None the domain is the interval from the smallest root to the largest. If [] the domain is the class domain. The default is [].

window

[{None, array_like}, optional] Window for the returned series. If None the class window is used. The default is None.

symbol

[str, optional] Symbol representing the independent variable. Default is 'x'.

Returns**new_series**

[series] Series with the specified roots.

method

`polynomial.chebyshev.Chebyshev.has_samecoef (other)`

Check if coefficients match.

Parameters**other**

[class instance] The other class must have the `coef` attribute.

Returns**bool**

[boolean] True if the coefficients are the same, False otherwise.

method

`polynomial.chebyshev.Chebyshev.has_samedomain (other)`

Check if domains match.

Parameters**other**

[class instance] The other class must have the `domain` attribute.

Returns**bool**

[boolean] True if the domains are the same, False otherwise.

method

`polynomial.chebyshev.Chebyshev.has_sametype (other)`

Check if types match.

Parameters**other**

[object] Class instance.

Returns**bool**

[boolean] True if other is same class as self

method

`polynomial.chebyshev.Chebyshev.has_samewindow (other)`

Check if windows match.

Parameters**other**

[class instance] The other class must have the `window` attribute.

Returns**bool**

[boolean] True if the windows are the same, False otherwise.

method

classmethod `polynomial.chebyshev.Chebyshev.identity` (*domain=None, window=None, symbol='x'*)

Identity function.

If p is the returned series, then $p(x) == x$ for all values of x .

Parameters

domain

[*None*, array_like], optional] If given, the array must be of the form [*beg*, *end*], where *beg* and *end* are the endpoints of the domain. If *None* is given then the class domain is used. The default is *None*.

window

[*None*, array_like], optional] If given, the resulting array must be if the form [*beg*, *end*], where *beg* and *end* are the endpoints of the window. If *None* is given then the class window is used. The default is *None*.

symbol

[str, optional] Symbol representing the independent variable. Default is 'x'.

Returns

new_series

[series] Series of representing the identity.

method

`polynomial.chebyshev.Chebyshev.integ` (*m=1, k=[], lbnd=None*)

Integrate.

Return a series instance that is the definite integral of the current series.

Parameters

m

[non-negative int] The number of integrations to perform.

k

[array_like] Integration constants. The first constant is applied to the first integration, the second to the second, and so on. The list of values must less than or equal to *m* in length and any missing values are set to zero.

lbnd

[Scalar] The lower bound of the definite integral.

Returns

new_series

[series] A new series representing the integral. The domain is the same as the domain of the integrated series.

method

classmethod `polynomial.chebyshev.Chebyshev.interpolate` (*func, deg, domain=None, args=()*)

Interpolate a function at the Chebyshev points of the first kind.

Returns the series that interpolates *func* at the Chebyshev points of the first kind scaled and shifted to the domain. The resulting series tends to a minmax approximation of *func* when the function is continuous in the domain.

Parameters

func

[function] The function to be interpolated. It must be a function of a single variable of the form $f(x, a, b, c \dots)$, where $a, b, c \dots$ are extra arguments passed in the *args* parameter.

deg

[int] Degree of the interpolating polynomial.

domain

[[None, [beg, end]], optional] Domain over which *func* is interpolated. The default is None, in which case the domain is [-1, 1].

args

[tuple, optional] Extra arguments to be used in the function call. Default is no extra arguments.

Returns**polynomial**

[Chebyshev instance] Interpolating Chebyshev instance.

Notes

See *numpy.polynomial.chebinterpolate* for more details.

method

`polynomial.Chebyshev.linspace (n=100, domain=None)`

Return x, y values at equally spaced points in domain.

Returns the x, y values at *n* linearly spaced points across the domain. Here y is the value of the polynomial at the points x. By default the domain is the same as that of the series instance. This method is intended mostly as a plotting aid.

Parameters**n**

[int, optional] Number of point pairs to return. The default value is 100.

domain

[[None, array_like], optional] If not None, the specified domain is used instead of that of the calling instance. It should be of the form [beg, end]. The default is None which case the class domain is used.

Returns**x, y**

[ndarray] x is equal to `linspace(self.domain[0], self.domain[1], n)` and y is the series evaluated at element of x.

method

`polynomial.Chebyshev.mapparms ()`

Return the mapping parameters.

The returned values define a linear map `off + scl*x` that is applied to the input arguments before the series is evaluated. The map depends on the `domain` and `window`; if the current `domain` is equal to the `window` the resulting map is the identity. If the coefficients of the series instance are to be used by themselves outside this class, then the linear function must be substituted for the `x` in the standard representation of the base polynomials.

Returns**off, scl**

[float or complex] The mapping function is defined by $\text{off} + \text{scl} * x$.

Notes

If the current domain is the interval $[l1, r1]$ and the window is $[l2, r2]$, then the linear mapping function L is defined by the equations:

$$\begin{aligned} L(l1) &= l2 \\ L(r1) &= r2 \end{aligned}$$

method

`polynomial.chebyshev.Chebyshev.roots()`

Return the roots of the series `polynomial`.

Compute the roots for the series. Note that the accuracy of the roots decreases the further outside the domain they lie.

Returns**roots**

[ndarray] Array containing the roots of the series.

method

`polynomial.chebyshev.Chebyshev.trim(tol=0)`

Remove trailing coefficients

Remove trailing coefficients until a coefficient is reached whose absolute value greater than *tol* or the beginning of the series is reached. If all the coefficients would be removed the series is set to `[0]`. A new series instance is returned with the new coefficients. The current instance remains unchanged.

Parameters**tol**

[non-negative number.] All trailing coefficients less than *tol* will be removed.

Returns**new_series**

[series] New instance of series with trimmed coefficients.

method

`polynomial.chebyshev.Chebyshev.truncate(size)`

Truncate series to length *size*.

Reduce the series to length *size* by discarding the high degree terms. The value of *size* must be a positive integer. This can be useful in least squares where the coefficients of the high degree terms may be very small.

Parameters**size**

[positive int] The series is reduced to length *size* by discarding the high degree terms. The value of *size* must be a positive integer.

Returns

new_series
[series] New instance of series with truncated coefficients.

Constants

<i>chebdomain</i>	ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None)
<i>chebzero</i>	ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None)
<i>chebone</i>	ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None)
<i>chebx</i>	ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None)

`polynomial.chebyshev.chebdomain = array([-1., 1.])`
ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None) –
ndarray(shape, dtype=np.float64, buffer=None, offset=0, strides=None, order=None)
An array object represents a multidimensional, homogeneous array of fixed-size items. An associated data-type object describes the format of each element in the array (its byte-order, how many bytes it occupies in memory, whether it is an integer, a floating point number, or something else, etc.)
Arrays should be constructed using *array*, *zeros* or *empty* (refer to the See Also section below). The parameters given here refer to a low-level method (*ndarray(...)*) for instantiating an array.
For more information, refer to the *numpy* module and examine the methods and attributes of an array.

Parameters

- (for the `__new__` method; see Notes below)
- shape**
[tuple of ints] Shape of created array.
- dtype**
[data-type, optional] Any object that can be interpreted as a numpy data type. Default is *numpy.float64*.
- buffer**
[object exposing buffer interface, optional] Used to fill the array with data.
- offset**
[int, optional] Offset of array data in buffer.
- strides**
[tuple of ints, optional] Strides of data in memory.
- order**
[{'C', 'F'}, optional] Row-major (C-style) or column-major (Fortran-style) order.

Attributes

- T**
[ndarray] Transpose of the array.
- data**
[buffer] The array's elements, in memory.

dtype

[dtype object] Describes the format of the elements in the array.

flags

[dict] Dictionary containing information related to memory use, e.g., 'C_CONTIGUOUS', 'OWNDATA', 'WRITEABLE', etc.

flat

[numpy.flatiter object] Flattened version of the array as an iterator. The iterator allows assignments, e.g., `x.flat = 3` (See [ndarray.flat](#) for assignment examples; TODO).

imag

[ndarray] Imaginary part of the array.

real

[ndarray] Real part of the array.

size

[int] Number of elements in the array.

itemsize

[int] The memory use of each array element in bytes.

nbytes

[int] The total number of bytes required to store the array data, i.e., `itemsize * size`.

ndim

[int] The array's number of dimensions.

shape

[tuple of ints] Shape of the array.

strides

[tuple of ints] The step-size required to move from one element to the next in memory. For example, a contiguous `(3, 4)` array of type `int16` in C-order has strides `(8, 2)`. This implies that to move from element to element in memory requires jumps of 2 bytes. To move from row-to-row, one needs to jump 8 bytes at a time (`2 * 4`).

ctypes

[ctypes object] Class containing properties of the array needed for interaction with ctypes.

base

[ndarray] If the array is a view into another array, that array is its *base* (unless that array is also a view). The *base* array is where the array data is actually stored.

See also:**`array`**

Construct an array.

`zeros`

Create an array, each element of which is zero.

`empty`

Create an array, but leave its allocated memory unchanged (i.e., it contains "garbage").

`dtype`

Create a data-type.

`numpy.typing.NDArray`

An ndarray alias *generic* w.r.t. its `dtype.type`.

Notes

There are two modes of creating an array using `__new__`:

1. If *buffer* is None, then only *shape*, *dtype*, and *order* are used.
2. If *buffer* is an object exposing the buffer interface, then all keywords are interpreted.

No `__init__` method is needed because the array is fully initialized after the `__new__` method.

Examples

These examples illustrate the low-level *ndarray* constructor. Refer to the *See Also* section above for easier ways of constructing an ndarray.

First mode, *buffer* is None:

```
>>> import numpy as np
>>> np.ndarray(shape=(2,2), dtype=np.float64, order='F')
array([[0.0e+000, 0.0e+000], # random
       [      nan, 2.5e-323]])
```

Second mode:

```
>>> np.ndarray((2,), buffer=np.array([1,2,3]),
...           offset=np.int_().itemsize,
...           dtype=np.int_) # offset = 1*itemsize, i.e. skip first element
array([2, 3])
```

```
polynomial.chebyshev.chebzero = array([0])
```

```
ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None) -
```

```
ndarray(shape, dtype=np.float64, buffer=None, offset=0, strides=None, order=None)
```

An array object represents a multidimensional, homogeneous array of fixed-size items. An associated data-type object describes the format of each element in the array (its byte-order, how many bytes it occupies in memory, whether it is an integer, a floating point number, or something else, etc.)

Arrays should be constructed using *array*, *zeros* or *empty* (refer to the *See Also* section below). The parameters given here refer to a low-level method (*ndarray(...)*) for instantiating an array.

For more information, refer to the *numpy* module and examine the methods and attributes of an array.

Parameters

(for the `__new__` method; see Notes below)

shape

[tuple of ints] Shape of created array.

dtype

[data-type, optional] Any object that can be interpreted as a numpy data type. Default is *numpy.float64*.

buffer

[object exposing buffer interface, optional] Used to fill the array with data.

offset

[int, optional] Offset of array data in buffer.

strides

[tuple of ints, optional] Strides of data in memory.

order

[{'C', 'F'}, optional] Row-major (C-style) or column-major (Fortran-style) order.

Attributes**T**

[ndarray] Transpose of the array.

data

[buffer] The array's elements, in memory.

dtype

[dtype object] Describes the format of the elements in the array.

flags

[dict] Dictionary containing information related to memory use, e.g., 'C_CONTIGUOUS', 'OWNDATA', 'WRITEABLE', etc.

flat

[numpy.flatiter object] Flattened version of the array as an iterator. The iterator allows assignments, e.g., `x.flat = 3` (See [ndarray.flat](#) for assignment examples; TODO).

imag

[ndarray] Imaginary part of the array.

real

[ndarray] Real part of the array.

size

[int] Number of elements in the array.

itemsize

[int] The memory use of each array element in bytes.

nbytes

[int] The total number of bytes required to store the array data, i.e., `itemsize * size`.

ndim

[int] The array's number of dimensions.

shape

[tuple of ints] Shape of the array.

strides

[tuple of ints] The step-size required to move from one element to the next in memory. For example, a contiguous `(3, 4)` array of type `int16` in C-order has strides `(8, 2)`. This implies that to move from element to element in memory requires jumps of 2 bytes. To move from row-to-row, one needs to jump 8 bytes at a time (`2 * 4`).

ctypes

[ctypes object] Class containing properties of the array needed for interaction with ctypes.

base

[ndarray] If the array is a view into another array, that array is its *base* (unless that array is also a view). The *base* array is where the array data is actually stored.

See also:**[array](#)**

Construct an array.

[zeros](#)

Create an array, each element of which is zero.

empty

Create an array, but leave its allocated memory unchanged (i.e., it contains “garbage”).

dtype

Create a data-type.

numpy.typing.NDArray

An ndarray alias *generic* w.r.t. its *dtype.type*.

Notes

There are two modes of creating an array using `__new__`:

1. If *buffer* is None, then only *shape*, *dtype*, and *order* are used.
2. If *buffer* is an object exposing the buffer interface, then all keywords are interpreted.

No `__init__` method is needed because the array is fully initialized after the `__new__` method.

Examples

These examples illustrate the low-level *ndarray* constructor. Refer to the *See Also* section above for easier ways of constructing an ndarray.

First mode, *buffer* is None:

```
>>> import numpy as np
>>> np.ndarray(shape=(2,2), dtype=np.float64, order='F')
array([[0.0e+000, 0.0e+000], # random
       [      nan, 2.5e-323]])
```

Second mode:

```
>>> np.ndarray((2,), buffer=np.array([1,2,3]),
...           offset=np.int_().itemsize,
...           dtype=np.int_) # offset = 1*itemsize, i.e. skip first element
array([2, 3])
```

```
polynomial.chebyshev.chebone = array([1])
```

`ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None) –`

`ndarray(shape, dtype=np.float64, buffer=None, offset=0, strides=None, order=None)`

An array object represents a multidimensional, homogeneous array of fixed-size items. An associated data-type object describes the format of each element in the array (its byte-order, how many bytes it occupies in memory, whether it is an integer, a floating point number, or something else, etc.)

Arrays should be constructed using *array*, *zeros* or *empty* (refer to the *See Also* section below). The parameters given here refer to a low-level method (*ndarray(...)*) for instantiating an array.

For more information, refer to the *numpy* module and examine the methods and attributes of an array.

Parameters

(for the `__new__` method; see Notes below)

shape

[tuple of ints] Shape of created array.

dtype

[data-type, optional] Any object that can be interpreted as a numpy data type. Default is `numpy.float64`.

buffer

[object exposing buffer interface, optional] Used to fill the array with data.

offset

[int, optional] Offset of array data in buffer.

strides

[tuple of ints, optional] Strides of data in memory.

order

[{'C', 'F'}, optional] Row-major (C-style) or column-major (Fortran-style) order.

Attributes**T**

[ndarray] Transpose of the array.

data

[buffer] The array's elements, in memory.

dtype

[dtype object] Describes the format of the elements in the array.

flags

[dict] Dictionary containing information related to memory use, e.g., 'C_CONTIGUOUS', 'OWNDATA', 'WRITEABLE', etc.

flat

[numpy.flatiter object] Flattened version of the array as an iterator. The iterator allows assignments, e.g., `x.flat = 3` (See `ndarray.flat` for assignment examples; TODO).

imag

[ndarray] Imaginary part of the array.

real

[ndarray] Real part of the array.

size

[int] Number of elements in the array.

itemsize

[int] The memory use of each array element in bytes.

nbytes

[int] The total number of bytes required to store the array data, i.e., `itemsize * size`.

ndim

[int] The array's number of dimensions.

shape

[tuple of ints] Shape of the array.

strides

[tuple of ints] The step-size required to move from one element to the next in memory. For example, a contiguous (3, 4) array of type `int16` in C-order has strides (8, 2). This implies that to move from element to element in memory requires jumps of 2 bytes. To move from row-to-row, one needs to jump 8 bytes at a time (2 * 4).

ctypes

[ctypes object] Class containing properties of the array needed for interaction with ctypes.

base

[ndarray] If the array is a view into another array, that array is its *base* (unless that array is also a view). The *base* array is where the array data is actually stored.

See also:**array**

Construct an array.

zeros

Create an array, each element of which is zero.

empty

Create an array, but leave its allocated memory unchanged (i.e., it contains “garbage”).

dtype

Create a data-type.

numpy.typing.NDArray

An ndarray alias *generic* w.r.t. its *dtype.type*.

Notes

There are two modes of creating an array using `__new__`:

1. If *buffer* is None, then only *shape*, *dtype*, and *order* are used.
2. If *buffer* is an object exposing the buffer interface, then all keywords are interpreted.

No `__init__` method is needed because the array is fully initialized after the `__new__` method.

Examples

These examples illustrate the low-level *ndarray* constructor. Refer to the *See Also* section above for easier ways of constructing an ndarray.

First mode, *buffer* is None:

```
>>> import numpy as np
>>> np.ndarray(shape=(2,2), dtype=np.float64, order='F')
array([[0.0e+000, 0.0e+000], # random
       [      nan, 2.5e-323]])
```

Second mode:

```
>>> np.ndarray((2,), buffer=np.array([1,2,3]),
...           offset=np.int_.itemsize,
...           dtype=np.int_) # offset = 1*itemsize, i.e. skip first element
array([2, 3])
```

```
polynomial.chebyshev.chebx = array([0, 1])
```

```
ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None) –
```

```
ndarray(shape, dtype=np.float64, buffer=None, offset=0, strides=None, order=None)
```

An array object represents a multidimensional, homogeneous array of fixed-size items. An associated data-type object describes the format of each element in the array (its byte-order, how many bytes it occupies in memory, whether it is an integer, a floating point number, or something else, etc.)

Arrays should be constructed using `array`, `zeros` or `empty` (refer to the See Also section below). The parameters given here refer to a low-level method (`ndarray(...)`) for instantiating an array.

For more information, refer to the `numpy` module and examine the methods and attributes of an array.

Parameters

(for the `__new__` method; see Notes below)

shape

[tuple of ints] Shape of created array.

dtype

[data-type, optional] Any object that can be interpreted as a numpy data type. Default is `numpy.float64`.

buffer

[object exposing buffer interface, optional] Used to fill the array with data.

offset

[int, optional] Offset of array data in buffer.

strides

[tuple of ints, optional] Strides of data in memory.

order

['C', 'F'], optional] Row-major (C-style) or column-major (Fortran-style) order.

Attributes

T

[ndarray] Transpose of the array.

data

[buffer] The array's elements, in memory.

dtype

[dtype object] Describes the format of the elements in the array.

flags

[dict] Dictionary containing information related to memory use, e.g., 'C_CONTIGUOUS', 'OWNDATA', 'WRITEABLE', etc.

flat

[numpy.flatiter object] Flattened version of the array as an iterator. The iterator allows assignments, e.g., `x.flat = 3` (See `ndarray.flat` for assignment examples; TODO).

imag

[ndarray] Imaginary part of the array.

real

[ndarray] Real part of the array.

size

[int] Number of elements in the array.

itemsize

[int] The memory use of each array element in bytes.

nbytes

[int] The total number of bytes required to store the array data, i.e., `itemsize * size`.

ndim

[int] The array's number of dimensions.

shape

[tuple of ints] Shape of the array.

strides

[tuple of ints] The step-size required to move from one element to the next in memory. For example, a contiguous (3, 4) array of type `int16` in C-order has strides (8, 2). This implies that to move from element to element in memory requires jumps of 2 bytes. To move from row-to-row, one needs to jump 8 bytes at a time ($2 * 4$).

ctypes

[ctypes object] Class containing properties of the array needed for interaction with ctypes.

base

[ndarray] If the array is a view into another array, that array is its *base* (unless that array is also a view). The *base* array is where the array data is actually stored.

See also:**`array`**

Construct an array.

`zeros`

Create an array, each element of which is zero.

`empty`

Create an array, but leave its allocated memory unchanged (i.e., it contains “garbage”).

`dtype`

Create a data-type.

`numpy.typing.NDArray`

An ndarray alias *generic* w.r.t. its `dtype.type`.

Notes

There are two modes of creating an array using `__new__`:

1. If *buffer* is None, then only *shape*, *dtype*, and *order* are used.
2. If *buffer* is an object exposing the buffer interface, then all keywords are interpreted.

No `__init__` method is needed because the array is fully initialized after the `__new__` method.

Examples

These examples illustrate the low-level `ndarray` constructor. Refer to the *See Also* section above for easier ways of constructing an ndarray.

First mode, *buffer* is None:

```
>>> import numpy as np
>>> np.ndarray(shape=(2,2), dtype=np.float64, order='F')
array([[0.0e+000, 0.0e+000], # random
       [      nan, 2.5e-323]])
```

Second mode:

```
>>> np.ndarray((2,), buffer=np.array([1,2,3]),
...           offset=np.int_().itemsize,
...           dtype=np.int_) # offset = 1*itemsize, i.e. skip first element
array([2, 3])
```

Arithmetic

<code>chebadd(c1, c2)</code>	Add one Chebyshev series to another.
<code>chebsub(c1, c2)</code>	Subtract one Chebyshev series from another.
<code>chebmulx(c)</code>	Multiply a Chebyshev series by x.
<code>chebmul(c1, c2)</code>	Multiply one Chebyshev series by another.
<code>chebdiv(c1, c2)</code>	Divide one Chebyshev series by another.
<code>chebpow(c, pow[, maxpower])</code>	Raise a Chebyshev series to a power.
<code>chebval(x, c[, tensor])</code>	Evaluate a Chebyshev series at points x.
<code>chebval2d(x, y, c)</code>	Evaluate a 2-D Chebyshev series at points (x, y).
<code>chebval3d(x, y, z, c)</code>	Evaluate a 3-D Chebyshev series at points (x, y, z).
<code>chebvalnd(pts, c)</code>	Evaluate an N-D Chebyshev series at points.
<code>chebgrid2d(x, y, c)</code>	Evaluate a 2-D Chebyshev series on the Cartesian product of x and y.
<code>chebgrid3d(x, y, z, c)</code>	Evaluate a 3-D Chebyshev series on the Cartesian product of x, y, and z.

`polynomial.chebyshev.chebadd(c1, c2)`

Add one Chebyshev series to another.

Returns the sum of two Chebyshev series $c1 + c2$. The arguments are sequences of coefficients ordered from lowest order term to highest, i.e., $[1,2,3]$ represents the series $T_0 + 2*T_1 + 3*T_2$.

Parameters

c1, c2

[array_like] 1-D arrays of Chebyshev series coefficients ordered from low to high.

Returns

out

[ndarray] Array representing the Chebyshev series of their sum.

See also:

[`chebsub`](#), [`chebmulx`](#), [`chebmul`](#), [`chebdiv`](#), [`chebpow`](#)

Notes

Unlike multiplication, division, etc., the sum of two Chebyshev series is a Chebyshev series (without having to “reproject” the result onto the basis set) so addition, just like that of “standard” polynomials, is simply “component-wise.”

Examples

```
>>> from numpy.polynomial import chebyshev as C
>>> c1 = (1, 2, 3)
>>> c2 = (3, 2, 1)
>>> C.chebadd(c1, c2)
array([4., 4., 4.])
```

`polynomial.chebyshev.chebsub(c1, c2)`

Subtract one Chebyshev series from another.

Returns the difference of two Chebyshev series $c1 - c2$. The sequences of coefficients are from lowest order term to highest, i.e., $[1, 2, 3]$ represents the series $T_0 + 2T_1 + 3T_2$.

Parameters

c1, c2

[array_like] 1-D arrays of Chebyshev series coefficients ordered from low to high.

Returns

out

[ndarray] Of Chebyshev series coefficients representing their difference.

See also:

[*chebadd*](#), [*chebmulx*](#), [*chebmul*](#), [*chebdiv*](#), [*chebpow*](#)

Notes

Unlike multiplication, division, etc., the difference of two Chebyshev series is a Chebyshev series (without having to “reproject” the result onto the basis set) so subtraction, just like that of “standard” polynomials, is simply “component-wise.”

Examples

```
>>> from numpy.polynomial import chebyshev as C
>>> c1 = (1, 2, 3)
>>> c2 = (3, 2, 1)
>>> C.chebsub(c1, c2)
array([-2.,  0.,  2.])
>>> C.chebsub(c2, c1) # -C.chebsub(c1, c2)
array([ 2.,  0., -2.])
```

`polynomial.chebyshev.chebmulx(c)`

Multiply a Chebyshev series by x .

Multiply the polynomial c by x , where x is the independent variable.

Parameters

c

[array_like] 1-D array of Chebyshev series coefficients ordered from low to high.

Returns

out

[ndarray] Array representing the result of the multiplication.

See also:

[*chebadd*](#), [*chebsub*](#), [*chebmul*](#), [*chebdiv*](#), [*chebpow*](#)

Examples

```
>>> from numpy.polynomial import chebyshev as C
>>> C.chebmulx([1,2,3])
array([1. , 2.5, 1. , 1.5])
```

`polynomial.chebyshev.chebmul(c1, c2)`

Multiply one Chebyshev series by another.

Returns the product of two Chebyshev series $c1 * c2$. The arguments are sequences of coefficients, from lowest order “term” to highest, e.g., [1,2,3] represents the series $T_0 + 2*T_1 + 3*T_2$.

Parameters

c1, c2

[array_like] 1-D arrays of Chebyshev series coefficients ordered from low to high.

Returns

out

[ndarray] Of Chebyshev series coefficients representing their product.

See also:

[*chebadd*](#), [*chebsub*](#), [*chebmulx*](#), [*chebdiv*](#), [*chebpow*](#)

Notes

In general, the (polynomial) product of two C-series results in terms that are not in the Chebyshev polynomial basis set. Thus, to express the product as a C-series, it is typically necessary to “reproject” the product onto said basis set, which typically produces “unintuitive live” (but correct) results; see Examples section below.

Examples

```
>>> from numpy.polynomial import chebyshev as C
>>> c1 = (1,2,3)
>>> c2 = (3,2,1)
>>> C.chebmul(c1,c2) # multiplication requires "reprojection"
array([ 6.5, 12. , 12. ,  4. ,  1.5])
```

`polynomial.chebyshev.chebdiv(c1, c2)`

Divide one Chebyshev series by another.

Returns the quotient-with-remainder of two Chebyshev series $c1 / c2$. The arguments are sequences of coefficients from lowest order “term” to highest, e.g., [1,2,3] represents the series $T_0 + 2*T_1 + 3*T_2$.

Parameters

c1, c2

[array_like] 1-D arrays of Chebyshev series coefficients ordered from low to high.

Returns

[quo, rem]

[ndarrays] Of Chebyshev series coefficients representing the quotient and remainder.

See also:

chebadd, chebsub, chebmulx, chebmul, chebpow

Notes

In general, the (polynomial) division of one C-series by another results in quotient and remainder terms that are not in the Chebyshev polynomial basis set. Thus, to express these results as C-series, it is typically necessary to “reproject” the results onto said basis set, which typically produces “unintuitive” (but correct) results; see Examples section below.

Examples

```
>>> from numpy.polynomial import chebyshev as C
>>> c1 = (1, 2, 3)
>>> c2 = (3, 2, 1)
>>> C.chebdiv(c1, c2) # quotient "intuitive," remainder not
(array([3.]), array([-8., -4.]))
>>> c2 = (0, 1, 2, 3)
>>> C.chebdiv(c2, c1) # neither "intuitive"
(array([0., 2.]), array([-2., -4.]))
```

`polynomial.chebyshev.chebpow(c, pow, maxpower=16)`

Raise a Chebyshev series to a power.

Returns the Chebyshev series *c* raised to the power *pow*. The argument *c* is a sequence of coefficients ordered from low to high. i.e., [1,2,3] is the series $T_0 + 2T_1 + 3T_2$.

Parameters

c

[array_like] 1-D array of Chebyshev series coefficients ordered from low to high.

pow

[integer] Power to which the series will be raised

maxpower

[integer, optional] Maximum power allowed. This is mainly to limit growth of the series to unmanageable size. Default is 16

Returns

coef

[ndarray] Chebyshev series of power.

See also:

chebadd, chebsub, chebmulx, chebmul, chebdiv

Examples

```
>>> from numpy.polynomial import chebyshev as C
>>> C.chebpow([1, 2, 3, 4], 2)
array([15.5, 22. , 16. , ..., 12.5, 12. , 8. ])
```

`polynomial.chebyshev.chebval(x, c, tensor=True)`

Evaluate a Chebyshev series at points x .

If c is of length $n + 1$, this function returns the value:

$$p(x) = c_0 * T_0(x) + c_1 * T_1(x) + \dots + c_n * T_n(x)$$

The parameter x is converted to an array only if it is a tuple or a list, otherwise it is treated as a scalar. In either case, either x or its elements must support multiplication and addition both with themselves and with the elements of c .

If c is a 1-D array, then $p(x)$ will have the same shape as x . If c is multidimensional, then the shape of the result depends on the value of *tensor*. If *tensor* is true the shape will be $c.shape[1:] + x.shape$. If *tensor* is false the shape will be $c.shape[1:]$. Note that scalars have shape $()$.

Trailing zeros in the coefficients will be used in the evaluation, so they should be avoided if efficiency is a concern.

Parameters

x

[array_like, compatible object] If x is a list or tuple, it is converted to an ndarray, otherwise it is left unchanged and treated as a scalar. In either case, x or its elements must support addition and multiplication with themselves and with the elements of c .

c

[array_like] Array of coefficients ordered so that the coefficients for terms of degree n are contained in $c[n]$. If c is multidimensional the remaining indices enumerate multiple polynomials. In the two dimensional case the coefficients may be thought of as stored in the columns of c .

tensor

[boolean, optional] If True, the shape of the coefficient array is extended with ones on the right, one for each dimension of x . Scalars have dimension 0 for this action. The result is that every column of coefficients in c is evaluated for every element of x . If False, x is broadcast over the columns of c for the evaluation. This keyword is useful when c is multidimensional. The default value is True.

Returns

values

[ndarray, algebra_like] The shape of the return value is described above.

See also:

[`chebval2d`](#), [`chebgrid2d`](#), [`chebval3d`](#), [`chebgrid3d`](#)

Notes

The evaluation uses Clenshaw recursion, aka synthetic division.

`polynomial.chebyshev.chebval2d(x, y, c)`

Evaluate a 2-D Chebyshev series at points (x, y).

This function returns the values:

$$p(x, y) = \sum_{i,j} c_{i,j} * T_i(x) * T_j(y)$$

The parameters x and y are converted to arrays only if they are tuples or a lists, otherwise they are treated as a scalars and they must have the same shape after conversion. In either case, either x and y or their elements must support multiplication and addition both with themselves and with the elements of c .

If c is a 1-D array a one is implicitly appended to its shape to make it 2-D. The shape of the result will be $c.shape[2:] + x.shape$.

Parameters

x, y

[array_like, compatible objects] The two dimensional series is evaluated at the points (x, y) , where x and y must have the same shape. If x or y is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and if it isn't an ndarray it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficient of the term of multi-degree i, j is contained in $c[i, j]$. If c has dimension greater than 2 the remaining indices enumerate multiple sets of coefficients.

Returns

values

[ndarray, compatible object] The values of the two dimensional Chebyshev series at points formed from pairs of corresponding values from x and y .

See also:

[*chebval*](#), [*chebgrid2d*](#), [*chebval3d*](#), [*chebgrid3d*](#)

`polynomial.chebyshev.chebval3d(x, y, z, c)`

Evaluate a 3-D Chebyshev series at points (x, y, z).

This function returns the values:

$$p(x, y, z) = \sum_{i,j,k} c_{i,j,k} * T_i(x) * T_j(y) * T_k(z)$$

The parameters x , y , and z are converted to arrays only if they are tuples or a lists, otherwise they are treated as a scalars and they must have the same shape after conversion. In either case, either x , y , and z or their elements must support multiplication and addition both with themselves and with the elements of c .

If c has fewer than 3 dimensions, ones are implicitly appended to its shape to make it 3-D. The shape of the result will be $c.shape[3:] + x.shape$.

Parameters

x, y, z

[array_like, compatible object] The three dimensional series is evaluated at the points (x, y, z) , where x , y , and z must have the same shape. If any of x , y , or z is a list or tuple, it is

first converted to an ndarray, otherwise it is left unchanged and if it isn't an ndarray it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficient of the term of multi-degree i, j, k is contained in $c[i, j, k]$. If c has dimension greater than 3 the remaining indices enumerate multiple sets of coefficients.

Returns

values

[ndarray, compatible object] The values of the multidimensional polynomial on points formed with triples of corresponding values from x , y , and z .

See also:

[*chebval*](#), [*chebval2d*](#), [*chebgrid2d*](#), [*chebgrid3d*](#)

`polynomial.chebyshev.chebvalnd` (pts, c)

Evaluate an N-D Chebyshev series at points.

This function returns the values:

$$p(pts, c) = \sum_{i_1, i_2, \dots, i_n} c_{i_1, i_2, \dots, i_n} * T_{i_1}(x_1) * T_{i_2}(x_2) \dots T_{i_n}(x_n)$$

where $x_1, x_2, \dots, x_n = pts$. Note that pts may also be an (n, m) array.

The parameters in pts are converted to arrays only if they are tuples or lists, otherwise they are treated as scalars and they must have the same shape after conversion. In either case, either the elements of pts or their elements must support multiplication and addition both with themselves and with the elements of c .

If c has fewer than N dimensions, ones are implicitly appended to its shape to make it N-D. The shape of the result will be $c.shape[N:] + pts[0].shape$.

Parameters

pts

[tuple or list of array_like, compatible objects] The N-dimensional series is evaluated at the points $(x_1, x_2, \dots, x_n)$ provided in the pts iterable, where all elements must have the same shape. If any element is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and if it isn't an ndarray it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficient of the term of multi-degree $i, j, k, \dots$ is contained in $c[i, j, k, \dots]$. If c has dimension greater than N, the remaining indices enumerate multiple sets of coefficients.

Returns

values

[ndarray, compatible object] The values of the multidimensional Chebyshev series on points formed with N-tuples of corresponding values from pts .

See also:

[*chebval*](#), [*chebval2d*](#), [*chebval3d*](#)

`polynomial.chebyshev.chebgrid2d(x, y, c)`

Evaluate a 2-D Chebyshev series on the Cartesian product of x and y .

This function returns the values:

$$p(a, b) = \sum_{i,j} c_{i,j} * T_i(a) * T_j(b),$$

where the points (a, b) consist of all pairs formed by taking a from x and b from y . The resulting points form a grid with x in the first dimension and y in the second.

The parameters x and y are converted to arrays only if they are tuples or a lists, otherwise they are treated as a scalars. In either case, either x and y or their elements must support multiplication and addition both with themselves and with the elements of c .

If c has fewer than two dimensions, ones are implicitly appended to its shape to make it 2-D. The shape of the result will be $c.shape[2:] + x.shape + y.shape$.

Parameters

x, y

[array_like, compatible objects] The two dimensional series is evaluated at the points in the Cartesian product of x and y . If x or y is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and, if it isn't an ndarray, it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficient of the term of multi-degree i, j is contained in $c[i, j]$. If c has dimension greater than two the remaining indices enumerate multiple sets of coefficients.

Returns

values

[ndarray, compatible object] The values of the two dimensional Chebyshev series at points in the Cartesian product of x and y .

See also:

[*chebval*](#), [*chebval2d*](#), [*chebval3d*](#), [*chebgrid3d*](#)

`polynomial.chebyshev.chebgrid3d(x, y, z, c)`

Evaluate a 3-D Chebyshev series on the Cartesian product of x , y , and z .

This function returns the values:

$$p(a, b, c) = \sum_{i,j,k} c_{i,j,k} * T_i(a) * T_j(b) * T_k(c)$$

where the points (a, b, c) consist of all triples formed by taking a from x , b from y , and c from z . The resulting points form a grid with x in the first dimension, y in the second, and z in the third.

The parameters x , y , and z are converted to arrays only if they are tuples or a lists, otherwise they are treated as a scalars. In either case, either x , y , and z or their elements must support multiplication and addition both with themselves and with the elements of c .

If c has fewer than three dimensions, ones are implicitly appended to its shape to make it 3-D. The shape of the result will be $c.shape[3:] + x.shape + y.shape + z.shape$.

Parameters

x, y, z

[array_like, compatible objects] The three dimensional series is evaluated at the points in the Cartesian product of x , y , and z . If x , y , or z is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and, if it isn't an ndarray, it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficients for terms of degree i, j are contained in $c[i, j]$. If c has dimension greater than two the remaining indices enumerate multiple sets of coefficients.

Returns**values**

[ndarray, compatible object] The values of the two dimensional polynomial at points in the Cartesian product of x and y .

Calculus

<i>chebder</i> (<i>c</i> [, <i>m</i> , <i>scl</i> , <i>axis</i>])	Differentiate a Chebyshev series.
<i>chebint</i> (<i>c</i> [, <i>m</i> , <i>k</i> , <i>lbnd</i> , <i>scl</i> , <i>axis</i>])	Integrate a Chebyshev series.

`polynomial.chebyshev.chebder` (*c*, *m*=1, *scl*=1, *axis*=0)

Differentiate a Chebyshev series.

Returns the Chebyshev series coefficients *c* differentiated *m* times along *axis*. At each iteration the result is multiplied by *scl* (the scaling factor is for use in a linear change of variable). The argument *c* is an array of coefficients from low to high degree along each axis, e.g., [1,2,3] represents the series $1 \cdot T_0 + 2 \cdot T_1 + 3 \cdot T_2$ while [[1,2],[1,2]] represents $1 \cdot T_0(x) \cdot T_0(y) + 1 \cdot T_1(x) \cdot T_0(y) + 2 \cdot T_0(x) \cdot T_1(y) + 2 \cdot T_1(x) \cdot T_1(y)$ if *axis*=0 is x and *axis*=1 is y .

Parameters**c**

[array_like] Array of Chebyshev series coefficients. If *c* is multidimensional the different axis correspond to different variables with the degree in each axis given by the corresponding index.

m

[int, optional] Number of derivatives taken, must be non-negative. (Default: 1)

scl

[scalar, optional] Each differentiation is multiplied by *scl*. The end result is multiplication by scl^m . This is for use in a linear change of variable. (Default: 1)

axis

[int, optional] Axis over which the derivative is taken. (Default: 0).

Returns**der**

[ndarray] Chebyshev series of the derivative.

See also:

[*chebint*](#)

Notes

In general, the result of differentiating a C-series needs to be “reprojected” onto the C-series basis set. Thus, typically, the result of this function is “unintuitive,” albeit correct; see Examples section below.

Examples

```
>>> from numpy.polynomial import chebyshev as C
>>> c = (1, 2, 3, 4)
>>> C.chebder(c)
array([14., 12., 24.])
>>> C.chebder(c, 3)
array([96.])
>>> C.chebder(c, scl=-1)
array([-14., -12., -24.])
>>> C.chebder(c, 2, -1)
array([12., 96.])
```

`polynomial.chebyshev.chebint` (*c*, *m*=1, *k*=[], *lbnd*=0, *scl*=1, *axis*=0)

Integrate a Chebyshev series.

Returns the Chebyshev series coefficients *c* integrated *m* times from *lbnd* along *axis*. At each iteration the resulting series is **multiplied** by *scl* and an integration constant, *k*, is added. The scaling factor is for use in a linear change of variable. (“Buyer beware”: note that, depending on what one is doing, one may want *scl* to be the reciprocal of what one might expect; for more information, see the Notes section below.) The argument *c* is an array of coefficients from low to high degree along each axis, e.g., [1,2,3] represents the series $T_0 + 2*T_1 + 3*T_2$ while [[1,2],[1,2]] represents $1*T_0(x)*T_0(y) + 1*T_1(x)*T_0(y) + 2*T_0(x)*T_1(y) + 2*T_1(x)*T_1(y)$ if *axis*=0 is *x* and *axis*=1 is *y*.

Parameters

- c**
[array_like] Array of Chebyshev series coefficients. If *c* is multidimensional the different axis correspond to different variables with the degree in each axis given by the corresponding index.
- m**
[int, optional] Order of integration, must be positive. (Default: 1)
- k**
[[], list, scalar], optional] Integration constant(s). The value of the first integral at zero is the first value in the list, the value of the second integral at zero is the second value, etc. If *k* == [] (the default), all constants are set to zero. If *m* == 1, a single scalar can be given instead of a list.
- lbnd**
[scalar, optional] The lower bound of the integral. (Default: 0)
- scl**
[scalar, optional] Following each integration the result is *multiplied* by *scl* before the integration constant is added. (Default: 1)
- axis**
[int, optional] Axis over which the integral is taken. (Default: 0).

Returns

- S**
[ndarray] C-series coefficients of the integral.

Raises**ValueError**

If $m < 1$, $\text{len}(k) > m$, $\text{np.ndim}(\text{lbnd}) \neq 0$, or $\text{np.ndim}(\text{scl}) \neq 0$.

See also:

[*chebder*](#)

Notes

Note that the result of each integration is *multiplied* by *scl*. Why is this important to note? Say one is making a linear change of variable $u = ax + b$ in an integral relative to x . Then $dx = du/a$, so one will need to set *scl* equal to $1/a$ - perhaps not what one would have first thought.

Also note that, in general, the result of integrating a C-series needs to be “reprojected” onto the C-series basis set. Thus, typically, the result of this function is “unintuitive,” albeit correct; see Examples section below.

Examples

```
>>> from numpy.polynomial import chebyshev as C
>>> c = (1,2,3)
>>> C.chebint(c)
array([ 0.5, -0.5,  0.5,  0.5])
>>> C.chebint(c,3)
array([ 0.03125, -0.1875,  0.04166667, -0.05208333,  0.01041667, # may vary
        0.00625])
>>> C.chebint(c, k=3)
array([ 3.5, -0.5,  0.5,  0.5])
>>> C.chebint(c, lbnd=-2)
array([ 8.5, -0.5,  0.5,  0.5])
>>> C.chebint(c, scl=-2)
array([-1.,  1., -1., -1.]
```

Misc Functions

<code>chebfromroots</code> (roots)	Generate a Chebyshev series with given roots.
<code>chebroots</code> (c)	Compute the roots of a Chebyshev series.
<code>chebvander</code> (x, deg)	Pseudo-Vandermonde matrix of given degree.
<code>chebvander2d</code> (x, y, deg)	Pseudo-Vandermonde matrix of given degrees.
<code>chebvander3d</code> (x, y, z, deg)	Pseudo-Vandermonde matrix of given degrees.
<code>chebgauss</code> (deg)	Gauss-Chebyshev quadrature.
<code>chebweight</code> (x)	The weight function of the Chebyshev polynomials.
<code>chebcompanion</code> (c)	Return the scaled companion matrix of c.
<code>chebfit</code> (x, y, deg[, rcond, full, w])	Least squares fit of Chebyshev series to data.
<code>chebpts1</code> (npts)	Chebyshev points of the first kind.
<code>chebpts2</code> (npts)	Chebyshev points of the second kind.
<code>chebtrim</code> (c[, tol])	Remove "small" "trailing" coefficients from a polynomial.
<code>chebline</code> (off, scl)	Chebyshev series whose graph is a straight line.
<code>cheb2poly</code> (c)	Convert a Chebyshev series to a polynomial.
<code>poly2cheb</code> (pol)	Convert a polynomial to a Chebyshev series.
<code>chebinterpolate</code> (func, deg[, args])	Interpolate a function at the Chebyshev points of the first kind.

`polynomial.chebyshev.chebfromroots`(roots)

Generate a Chebyshev series with given roots.

The function returns the coefficients of the polynomial

$$p(x) = (x - r_0) * (x - r_1) * ... * (x - r_n),$$

in Chebyshev form, where the r_n are the roots specified in `roots`. If a zero has multiplicity n , then it must appear in `roots` n times. For instance, if 2 is a root of multiplicity three and 3 is a root of multiplicity 2, then `roots` looks something like [2, 2, 2, 3, 3]. The roots can appear in any order.

If the returned coefficients are c , then

$$p(x) = c_0 + c_1 * T_1(x) + ... + c_n * T_n(x)$$

The coefficient of the last term is not generally 1 for monic polynomials in Chebyshev form.

Parameters

roots

[array_like] Sequence containing the roots.

Returns

out

[ndarray] 1-D array of coefficients. If all roots are real then `out` is a real array, if some of the roots are complex, then `out` is complex even if all the coefficients in the result are real (see Examples below).

See also:

`numpy.polynomial.polynomial.polyfromroots`
`numpy.polynomial.legendre.legfromroots`
`numpy.polynomial.laguerre.lagfromroots`
`numpy.polynomial.hermite.hermfromroots`
`numpy.polynomial.hermite_e.hermefromroots`

Examples

```
>>> import numpy.polynomial.chebyshev as C
>>> C.chebfromroots((-1,0,1)) # x^3 - x relative to the standard basis
array([ 0. , -0.25,  0. ,  0.25])
>>> j = complex(0,1)
>>> C.chebfromroots((-j,j)) # x^2 + 1 relative to the standard basis
array([1.5+0.j, 0. +0.j, 0.5+0.j])
```

`polynomial.chebyshev.chebroots(c)`

Compute the roots of a Chebyshev series.

Return the roots (a.k.a. “zeros”) of the polynomial

$$p(x) = \sum_i c[i] * T_i(x).$$

Parameters

c
[1-D array_like] 1-D array of coefficients.

Returns

out
[ndarray] Array of the roots of the series. If all the roots are real, then *out* is also real, otherwise it is complex.

See also:

`numpy.polynomial.polynomial.polyroots`
`numpy.polynomial.legendre.legroots`
`numpy.polynomial.laguerre.lagroots`
`numpy.polynomial.hermite.hermroots`
`numpy.polynomial.hermite_e.hermroots`

Notes

The root estimates are obtained as the eigenvalues of the companion matrix, Roots far from the origin of the complex plane may have large errors due to the numerical instability of the series for such values. Roots with multiplicity greater than 1 will also show larger errors as the value of the series near such points is relatively insensitive to errors in the roots. Isolated roots near the origin can be improved by a few iterations of Newton’s method.

The Chebyshev series basis polynomials aren’t powers of x so the results of this function may seem unintuitive.

Examples

```
>>> import numpy.polynomial.chebyshev as cheb
>>> cheb.chebroots((-1, 1, -1, 1)) # T3 - T2 + T1 - T0 has real roots
array([-5.00000000e-01,  2.60860684e-17,  1.00000000e+00]) # may vary
```

`polynomial.chebyshev.chebvander(x, deg)`

Pseudo-Vandermonde matrix of given degree.

Returns the pseudo-Vandermonde matrix of degree *deg* and sample points *x*. The pseudo-Vandermonde matrix is defined by

$$V[\dots, i] = T_i(x),$$

where $0 \leq i \leq \text{deg}$. The leading indices of *V* index the elements of *x* and the last index is the degree of the Chebyshev polynomial.

If *c* is a 1-D array of coefficients of length $n + 1$ and *V* is the matrix $V = \text{chebvander}(x, n)$, then `np.dot(V, c)` and `chebval(x, c)` are the same up to roundoff. This equivalence is useful both for least squares fitting and for the evaluation of a large number of Chebyshev series of the same degree and sample points.

Parameters

- x**
[array_like] Array of points. The dtype is converted to float64 or complex128 depending on whether any of the elements are complex. If *x* is scalar it is converted to a 1-D array.
- deg**
[int] Degree of the resulting matrix.

Returns

- vander**
[ndarray] The pseudo Vandermonde matrix. The shape of the returned matrix is `x.shape + (deg + 1,)`, where The last index is the degree of the corresponding Chebyshev polynomial. The dtype will be the same as the converted *x*.

`polynomial.chebyshev.chebvander2d(x, y, deg)`

Pseudo-Vandermonde matrix of given degrees.

Returns the pseudo-Vandermonde matrix of degrees *deg* and sample points *(x, y)*. The pseudo-Vandermonde matrix is defined by

$$V[\dots, (\text{deg}[1] + 1) * i + j] = T_i(x) * T_j(y),$$

where $0 \leq i \leq \text{deg}[0]$ and $0 \leq j \leq \text{deg}[1]$. The leading indices of *V* index the points *(x, y)* and the last index encodes the degrees of the Chebyshev polynomials.

If $V = \text{chebvander2d}(x, y, [\text{xdeg}, \text{ydeg}])$, then the columns of *V* correspond to the elements of a 2-D coefficient array *c* of shape $(\text{xdeg} + 1, \text{ydeg} + 1)$ in the order

$$c_{00}, c_{01}, c_{02}, \dots, c_{10}, c_{11}, c_{12}, \dots$$

and `np.dot(V, c.flat)` and `chebval2d(x, y, c)` will be the same up to roundoff. This equivalence is useful both for least squares fitting and for the evaluation of a large number of 2-D Chebyshev series of the same degrees and sample points.

Parameters

- x, y**
[array_like] Arrays of point coordinates, all of the same shape. The dtypes will be converted to either float64 or complex128 depending on whether any of the elements are complex. Scalars are converted to 1-D arrays.
- deg**
[list of ints] List of maximum degrees of the form `[x_deg, y_deg]`.

Returns

vander2d

[ndarray] The shape of the returned matrix is `x.shape + (order,)`, where `order = (deg[0] + 1) * (deg[1] + 1)`. The dtype will be the same as the converted `x` and `y`.

See also:

[*chebvander*](#), [*chebvander3d*](#), [*chebval2d*](#), [*chebval3d*](#)

`polynomial.chebyshev.chebvander3d(x, y, z, deg)`

Pseudo-Vandermonde matrix of given degrees.

Returns the pseudo-Vandermonde matrix of degrees `deg` and sample points `(x, y, z)`. If `l, m, n` are the given degrees in `x, y, z`, then The pseudo-Vandermonde matrix is defined by

$$V[...,(m+1)(n+1)i + (n+1)j + k] = T_i(x) * T_j(y) * T_k(z),$$

where $0 \leq i \leq l, 0 \leq j \leq m$, and $0 \leq k \leq n$. The leading indices of `V` index the points `(x, y, z)` and the last index encodes the degrees of the Chebyshev polynomials.

If `V = chebvander3d(x, y, z, [xdeg, ydeg, zdeg])`, then the columns of `V` correspond to the elements of a 3-D coefficient array `c` of shape `(xdeg + 1, ydeg + 1, zdeg + 1)` in the order

$$c_{000}, c_{001}, c_{002}, \dots, c_{010}, c_{011}, c_{012}, \dots$$

and `np.dot(V, c.flat)` and `chebval3d(x, y, z, c)` will be the same up to roundoff. This equivalence is useful both for least squares fitting and for the evaluation of a large number of 3-D Chebyshev series of the same degrees and sample points.

Parameters**x, y, z**

[array_like] Arrays of point coordinates, all of the same shape. The dtypes will be converted to either float64 or complex128 depending on whether any of the elements are complex. Scalars are converted to 1-D arrays.

deg

[list of ints] List of maximum degrees of the form `[x_deg, y_deg, z_deg]`.

Returns**vander3d**

[ndarray] The shape of the returned matrix is `x.shape + (order,)`, where `order = (deg[0] + 1) * (deg[1] + 1) * (deg[2] + 1)`. The dtype will be the same as the converted `x, y`, and `z`.

See also:

[*chebvander*](#), [*chebvander3d*](#), [*chebval2d*](#), [*chebval3d*](#)

`polynomial.chebyshev.chebgauss(deg)`

Gauss-Chebyshev quadrature.

Computes the sample points and weights for Gauss-Chebyshev quadrature. These sample points and weights will correctly integrate polynomials of degree $2 * deg - 1$ or less over the interval $[-1, 1]$ with the weight function $f(x) = 1/\sqrt{1 - x^2}$.

Parameters**deg**

[int] Number of sample points and weights. It must be ≥ 1 .

Returns

- x**
[ndarray] 1-D ndarray containing the sample points.
- y**
[ndarray] 1-D ndarray containing the weights.

Notes

The results have only been tested up to degree 100, higher degrees may be problematic. For Gauss-Chebyshev there are closed form solutions for the sample points and weights. If $n = \text{deg}$, then

$$x_i = \cos(\pi(2i - 1)/(2n))$$

$$w_i = \pi/n$$

`polynomial.chebyshev.chebweight(x)`

The weight function of the Chebyshev polynomials.

The weight function is $1/\sqrt{1-x^2}$ and the interval of integration is $[-1, 1]$. The Chebyshev polynomials are orthogonal, but not normalized, with respect to this weight function.

Parameters

- x**
[array_like] Values at which the weight function will be computed.

Returns

- w**
[ndarray] The weight function at x .

`polynomial.chebyshev.chebcompanion(c)`

Return the scaled companion matrix of c .

The basis polynomials are scaled so that the companion matrix is symmetric when c is a Chebyshev basis polynomial. This provides better eigenvalue estimates than the unscaled case and for basis polynomials the eigenvalues are guaranteed to be real if `numpy.linalg.eigvalsh` is used to obtain them.

Parameters

- c**
[array_like] 1-D array of Chebyshev series coefficients ordered from low to high degree.

Returns

- mat**
[ndarray] Scaled companion matrix of dimensions (deg, deg).

`polynomial.chebyshev.chebfit(x, y, deg, rcond=None, full=False, w=None)`

Least squares fit of Chebyshev series to data.

Return the coefficients of a Chebyshev series of degree deg that is the least squares fit to the data values y given at points x . If y is 1-D the returned coefficients will also be 1-D. If y is 2-D multiple fits are done, one for each column of y , and the resulting coefficients are stored in the corresponding columns of a 2-D return. The fitted polynomial(s) are in the form

$$p(x) = c_0 + c_1 * T_1(x) + \dots + c_n * T_n(x),$$

where n is deg .

Parameters

- x**
[array_like, shape (M,)] x-coordinates of the M sample points ($x[i]$, $y[i]$).
- y**
[array_like, shape (M,) or (M, K)] y-coordinates of the sample points. Several data sets of sample points sharing the same x-coordinates can be fitted at once by passing in a 2D-array that contains one dataset per column.
- deg**
[int or 1-D array_like] Degree(s) of the fitting polynomials. If *deg* is a single integer, all terms up to and including the *deg*'th term are included in the fit. For NumPy versions $\geq 1.11.0$ a list of integers specifying the degrees of the terms to include may be used instead.
- rcond**
[float, optional] Relative condition number of the fit. Singular values smaller than this relative to the largest singular value will be ignored. The default value is $\text{len}(x) * \text{eps}$, where *eps* is the relative precision of the float type, about $2e-16$ in most cases.
- full**
[bool, optional] Switch determining nature of return value. When it is False (the default) just the coefficients are returned, when True diagnostic information from the singular value decomposition is also returned.
- w**
[array_like, shape (M,), optional] Weights. If not None, the weight $w[i]$ applies to the unsquared residual $y[i] - \hat{y}[i]$ at $x[i]$. Ideally the weights are chosen so that the errors of the products $w[i] * y[i]$ all have the same variance. When using inverse-variance weighting, use $w[i] = 1/\text{sigma}(y[i])$. The default value is None.

Returns

- coef**
[ndarray, shape (M,) or (M, K)] Chebyshev coefficients ordered from low to high. If *y* was 2-D, the coefficients for the data in column *k* of *y* are in column *k*.

[residuals, rank, singular_values, rcond]

[list] These values are only returned if `full == True`

- residuals – sum of squared residuals of the least squares fit
- rank – the numerical rank of the scaled Vandermonde matrix
- singular_values – singular values of the scaled Vandermonde matrix
- rcond – value of *rcond*.

For more details, see [`numpy.linalg.lstsq`](#).

Warns**RankWarning**

The rank of the coefficient matrix in the least-squares fit is deficient. The warning is only raised if `full == False`. The warnings can be turned off by

```
>>> import warnings
>>> warnings.simplefilter('ignore', np.exceptions.RankWarning)
```

See also:

`numpy.polynomial.polynomial.polyfit`
`numpy.polynomial.legendre.legfit`
`numpy.polynomial.laguerre.lagfit`
`numpy.polynomial.hermite.hermfit`
`numpy.polynomial.hermite_e.hermefit`
`chebval`

Evaluates a Chebyshev series.

`chebvander`

Vandermonde matrix of Chebyshev series.

`chebweight`

Chebyshev weight function.

`numpy.linalg.lstsq`

Computes a least-squares fit from the matrix.

`scipy.interpolate.UnivariateSpline`

Computes spline fits.

Notes

The solution is the coefficients of the Chebyshev series p that minimizes the sum of the weighted squared errors

$$E = \sum_j w_j^2 * |y_j - p(x_j)|^2,$$

where w_j are the weights. This problem is solved by setting up as the (typically) overdetermined matrix equation

$$V(x) * c = w * y,$$

where V is the weighted pseudo Vandermonde matrix of x , c are the coefficients to be solved for, w are the weights, and y are the observed values. This equation is then solved using the singular value decomposition of V .

If some of the singular values of V are so small that they are neglected, then a `RankWarning` will be issued. This means that the coefficient values may be poorly determined. Using a lower order fit will usually get rid of the warning. The `rcond` parameter can also be set to a value smaller than its default, but the resulting fit may be spurious and have large contributions from roundoff error.

Fits using Chebyshev series are usually better conditioned than fits using power series, but much can depend on the distribution of the sample points and the smoothness of the data. If the quality of the fit is inadequate splines may be a good alternative.

References

[1]

`polynomial.chebyshev.chebpts1` (*npts*)

Chebyshev points of the first kind.

The Chebyshev points of the first kind are the points $\cos(x)$, where $x = [\pi * (k + .5) / npts]$ for k in `range(npts)`.

Parameters

npts

[int] Number of sample points desired.

Returns

pts

[ndarray] The Chebyshev points of the first kind.

See also:*[chebpts2](#)*`polynomial.chebyshev.chebpts2(npts)`

Chebyshev points of the second kind.

The Chebyshev points of the second kind are the points $\cos(x)$, where $x = [\pi*k/(npts - 1)$ for k in $\text{range}(npts)]$ sorted in ascending order.

Parameters**npts**

[int] Number of sample points desired.

Returns**pts**

[ndarray] The Chebyshev points of the second kind.

`polynomial.chebyshev.chebtrim(c, tol=0)`

Remove “small” “trailing” coefficients from a polynomial.

“Small” means “small in absolute value” and is controlled by the parameter *tol*; “trailing” means highest order coefficient(s), e.g., in `[0, 1, 1, 0, 0]` (which represents $0 + x + x^2 + 0*x^3 + 0*x^4$) both the 3-rd and 4-th order coefficients would be “trimmed.”

Parameters**c**

[array_like] 1-d array of coefficients, ordered from lowest order to highest.

tol[number, optional] Trailing (i.e., highest order) elements with absolute value less than or equal to *tol* (default value is zero) are removed.**Returns****trimmed**

[ndarray] 1-d array with trailing zeros removed. If the resulting series would be empty, a series containing a single zero is returned.

Raises**ValueError**If *tol* < 0**Examples**

```
>>> from numpy.polynomial import polyutils as pu
>>> pu.trimcoef((0,0,3,0,5,0,0))
array([0., 0., 3., 0., 5.])
>>> pu.trimcoef((0,0,1e-3,0,1e-5,0,0),1e-3) # item == tol is trimmed
array([0.])
>>> i = complex(0,1) # works for complex
>>> pu.trimcoef((3e-4,1e-3*(1-i),5e-4,2e-5*(1+i)), 1e-3)
array([0.0003+0.j, 0.001 -0.001j])
```

`polynomial.chebyshev.chebline` (*off*, *scl*)

Chebyshev series whose graph is a straight line.

Parameters

off, scl

[scalars] The specified line is given by $\text{off} + \text{scl} \cdot x$.

Returns

y

[ndarray] This module's representation of the Chebyshev series for $\text{off} + \text{scl} \cdot x$.

Examples

```
>>> import numpy.polynomial.chebyshev as C
>>> C.chebline(3,2)
array([3, 2])
>>> C.chebval(-3, C.chebline(3,2)) # should be -3
-3.0
```

`polynomial.chebyshev.cheb2poly` (*c*)

Convert a Chebyshev series to a polynomial.

Convert an array representing the coefficients of a Chebyshev series, ordered from lowest degree to highest, to an array of the coefficients of the equivalent polynomial (relative to the “standard” basis) ordered from lowest to highest degree.

Parameters

c

[array_like] 1-D array containing the Chebyshev series coefficients, ordered from lowest order term to highest.

Returns

pol

[ndarray] 1-D array containing the coefficients of the equivalent polynomial (relative to the “standard” basis) ordered from lowest order term to highest.

See also:

`poly2cheb`

Notes

The easy way to do conversions between polynomial basis sets is to use the `convert` method of a class instance.

Examples

```
>>> from numpy import polynomial as P
>>> c = P.Chebyshev(range(4))
>>> c
Chebyshev([0., 1., 2., 3.], domain=[-1., 1.], window=[-1., 1.], symbol='x')
>>> p = c.convert(kind=P.Polynomial)
>>> p
Polynomial([-2., -8., 4., 12.], domain=[-1., 1.], window=[-1., 1.], ...)
>>> P.chebyshev.cheb2poly(range(4))
array([-2., -8., 4., 12.])
```

`polynomial.chebyshev.poly2cheb(pol)`

Convert a polynomial to a Chebyshev series.

Convert an array representing the coefficients of a polynomial (relative to the “standard” basis) ordered from lowest degree to highest, to an array of the coefficients of the equivalent Chebyshev series, ordered from lowest to highest degree.

Parameters

pol

[array_like] 1-D array containing the polynomial coefficients

Returns

c

[ndarray] 1-D array containing the coefficients of the equivalent Chebyshev series.

See also:

[*cheb2poly*](#)

Notes

The easy way to do conversions between polynomial basis sets is to use the `convert` method of a class instance.

Examples

```
>>> from numpy import polynomial as P
>>> p = P.Polynomial(range(4))
>>> p
Polynomial([0., 1., 2., 3.], domain=[-1., 1.], window=[-1., 1.], symbol='x')
>>> c = p.convert(kind=P.Chebyshev)
>>> c
Chebyshev([1. , 3.25, 1. , 0.75], domain=[-1., 1.], window=[-1., ...
>>> P.chebyshev.poly2cheb(range(4))
array([1. , 3.25, 1. , 0.75])
```

`polynomial.chebyshev.chebinterpolate` (*func*, *deg*, *args=()*)

Interpolate a function at the Chebyshev points of the first kind.

Returns the Chebyshev series that interpolates *func* at the Chebyshev points of the first kind in the interval $[-1, 1]$. The interpolating series tends to a minmax approximation to *func* with increasing *deg* if the function is continuous in the interval.

Parameters

func

[function] The function to be approximated. It must be a function of a single variable of the form $f(x, a, b, c, \dots)$, where $a, b, c, \dots$ are extra arguments passed in the *args* parameter.

deg

[int] Degree of the interpolating polynomial

args

[tuple, optional] Extra arguments to be used in the function call. Default is no extra arguments.

Returns

coef

[ndarray, shape (deg + 1,)] Chebyshev coefficients of the interpolating series ordered from low to high.

Notes

The Chebyshev polynomials used in the interpolation are orthogonal when sampled at the Chebyshev points of the first kind. If it is desired to constrain some of the coefficients they can simply be set to the desired value after the interpolation, no new interpolation or fit is needed. This is especially useful if it is known apriori that some of coefficients are zero. For instance, if the function is even then the coefficients of the terms of odd degree in the result can be set to zero.

Examples

```
>>> import numpy.polynomial.chebyshev as C
>>> C.chebinterpolate(lambda x: np.tanh(x) + 0.5, 8)
array([ 5.00000000e-01,  8.11675684e-01, -9.86864911e-17,
        -5.42457905e-02, -2.71387850e-16,  4.51658839e-03,
         2.46716228e-17, -3.79694221e-04, -3.26899002e-16])
```

`numpy.polynomial`

Notes

The implementations of multiplication, division, integration, and differentiation use the algebraic identities [1]:

$$T_n(x) = \frac{z^n + z^{-n}}{2}$$
$$z \frac{dx}{dz} = \frac{z - z^{-1}}{2}.$$

where

$$x = \frac{z + z^{-1}}{2}.$$

These identities allow a Chebyshev series to be expressed as a finite, symmetric Laurent series. In this module, this sort of Laurent series is referred to as a “z-series.”

References

Hermite Series, “Physicists” (`numpy.polynomial.hermite`)

This module provides a number of objects (mostly functions) useful for dealing with Hermite series, including a *Hermite* class that encapsulates the usual arithmetic operations. (General information on how this module represents and works with such polynomials is in the docstring for its “parent” sub-package, *numpy.polynomial*).

Classes

<i>Hermite</i> (coef[, domain, window, symbol])	A Hermite series class.
---	-------------------------

class `numpy.polynomial.hermite.Hermite` (coef, domain=None, window=None, symbol='x')

A Hermite series class.

The Hermite class provides the standard Python numerical methods ‘+’, ‘-’, ‘*’, ‘/’, ‘%’, ‘divmod’, ‘**’, and ‘()’ as well as the attributes and methods listed below.

Parameters

coef

[array_like] Hermite coefficients in order of increasing degree, i.e. (1, 2, 3) gives $1 * H_0(x) + 2 * H_1(x) + 3 * H_2(x)$.

domain

[(2,) array_like, optional] Domain to use. The interval [domain[0], domain[1]] is mapped to the interval [window[0], window[1]] by shifting and scaling. The default value is [-1., 1.].

window

[(2,) array_like, optional] Window, see domain for its use. The default value is [-1., 1.].

symbol

[str, optional] Symbol used to represent the independent variable in string representations of the polynomial expression, e.g. for printing. The symbol must be a valid Python identifier. Default value is ‘x’.

New in version 1.24.

Attributes**symbol****Methods**

<code>__call__(arg)</code>	Call self as a function.
<code>basis(deg[, domain, window, symbol])</code>	Series basis polynomial of degree <i>deg</i> .
<code>cast(series[, domain, window])</code>	Convert series to series of this class.
<code>convert([domain, kind, window])</code>	Convert series to a different kind and/or domain and/or window.
<code>copy()</code>	Return a copy.
<code>cutdeg(deg)</code>	Truncate series to the given degree.
<code>degree()</code>	The degree of the series.
<code>deriv([m])</code>	Differentiate.
<code>fit(x, y, deg[, domain, rcond, full, w, ...])</code>	Least squares fit to data.
<code>fromroots(roots[, domain, window, symbol])</code>	Return series instance that has the specified roots.
<code>has_samecoef(other)</code>	Check if coefficients match.
<code>has_samedomain(other)</code>	Check if domains match.
<code>has_sametype(other)</code>	Check if types match.
<code>has_samewindow(other)</code>	Check if windows match.
<code>identity([domain, window, symbol])</code>	Identity function.
<code>integ([m, k, lbnd])</code>	Integrate.
<code>linspace([n, domain])</code>	Return x, y values at equally spaced points in domain.
<code>mapparms()</code>	Return the mapping parameters.
<code>roots()</code>	Return the roots of the series polynomial.
<code>trim([tol])</code>	Remove trailing coefficients
<code>truncate(size)</code>	Truncate series to length <i>size</i> .

method

`polynomial.hermite.Hermite.__call__(arg)`

Call self as a function.

method

classmethod `polynomial.hermite.Hermite.basis(deg, domain=None, window=None, symbol='x')`

Series basis polynomial of degree *deg*.Returns the series representing the basis polynomial of degree *deg*.**Parameters****deg**[int] Degree of the basis polynomial for the series. Must be ≥ 0 .**domain**

[[None, array_like], optional] If given, the array must be of the form `[beg, end]`, where *beg* and *end* are the endpoints of the domain. If None is given then the class domain is used. The default is None.

window

[[None, array_like], optional] If given, the resulting array must be if the form `[beg, end]`, where *beg* and *end* are the endpoints of the window. If None is given then the class window is used. The default is None.

symbol

[str, optional] Symbol representing the independent variable. Default is 'x'.

Returns**new_series**

[series] A series with the coefficient of the *deg* term set to one and all others zero.

method

classmethod `polynomial.hermite.Hermite.cast(series, domain=None, window=None)`

Convert series to series of this class.

The *series* is expected to be an instance of some polynomial series of one of the types supported by the `numpy.polynomial` module, but could be some other class that supports the `convert` method.

Parameters**series**

[series] The series instance to be converted.

domain

[{None, array_like}, optional] If given, the array must be of the form `[beg, end]`, where `beg` and `end` are the endpoints of the domain. If `None` is given then the class domain is used. The default is `None`.

window

[{None, array_like}, optional] If given, the resulting array must be of the form `[beg, end]`, where `beg` and `end` are the endpoints of the window. If `None` is given then the class window is used. The default is `None`.

Returns**new_series**

[series] A series of the same kind as the calling class and equal to *series* when evaluated.

See also:***convert***

similar instance method

method

`polynomial.hermite.Hermite.convert(domain=None, kind=None, window=None)`

Convert series to a different kind and/or domain and/or window.

Parameters**domain**

[array_like, optional] The domain of the converted series. If the value is `None`, the default domain of *kind* is used.

kind

[class, optional] The polynomial series type class to which the current instance should be converted. If *kind* is `None`, then the class of the current instance is used.

window

[array_like, optional] The window of the converted series. If the value is `None`, the default window of *kind* is used.

Returns

new_series

[series] The returned class can be of different type than the current instance and/or have a different domain and/or different window.

Notes

Conversion between domains and class types can result in numerically ill defined series.

method

`polynomial.hermite.Hermite.copy()`

Return a copy.

Returns**new_series**

[series] Copy of self.

method

`polynomial.hermite.Hermite.cutdeg(deg)`

Truncate series to the given degree.

Reduce the degree of the series to *deg* by discarding the high order terms. If *deg* is greater than the current degree a copy of the current series is returned. This can be useful in least squares where the coefficients of the high degree terms may be very small.

Parameters**deg**

[non-negative int] The series is reduced to degree *deg* by discarding the high order terms. The value of *deg* must be a non-negative integer.

Returns**new_series**

[series] New instance of series with reduced degree.

method

`polynomial.hermite.Hermite.degree()`

The degree of the series.

Returns**degree**

[int] Degree of the series, one less than the number of coefficients.

Examples

Create a polynomial object for $1 + 7x + 4x^2$:

```
>>> np.polynomial.set_default_printstyle("unicode")
>>> poly = np.polynomial.Polynomial([1, 7, 4])
>>> print(poly)
1.0 + 7.0·x + 4.0·x2
>>> poly.degree()
2
```

Note that this method does not check for non-zero coefficients. You must trim the polynomial to remove any trailing zeroes:

```
>>> poly = np.polynomial.Polynomial([1, 7, 0])
>>> print(poly)
1.0 + 7.0·x + 0.0·x2
>>> poly.degree()
2
>>> poly.trim().degree()
1
```

method

`polynomial.hermite.Hermite.deriv(m=1)`

Differentiate.

Return a series instance of that is the derivative of the current series.

Parameters

m

[non-negative int] Find the derivative of order *m*.

Returns

new_series

[series] A new series representing the derivative. The domain is the same as the domain of the differentiated series.

method

classmethod `polynomial.hermite.Hermite.fit(x, y, deg, domain=None, rcond=None, full=False, w=None, window=None, symbol='x')`

Least squares fit to data.

Return a series instance that is the least squares fit to the data *y* sampled at *x*. The domain of the returned instance can be specified and this will often result in a superior fit with less chance of ill conditioning.

Parameters

x

[array_like, shape (M,)] x-coordinates of the M sample points (*x*[*i*], *y*[*i*]).

y

[array_like, shape (M,)] y-coordinates of the M sample points (*x*[*i*], *y*[*i*]).

deg

[int or 1-D array_like] Degree(s) of the fitting polynomials. If *deg* is a single integer all terms up to and including the *deg*'th term are included in the fit. For NumPy versions $\geq 1.11.0$ a list of integers specifying the degrees of the terms to include may be used instead.

domain

[{None, [beg, end], []}, optional] Domain to use for the returned series. If *None*, then a minimal domain that covers the points *x* is chosen. If [] the class domain is used. The default value was the class domain in NumPy 1.4 and *None* in later versions. The [] option was added in numpy 1.5.0.

rcond

[float, optional] Relative condition number of the fit. Singular values smaller than this relative to the largest singular value will be ignored. The default value is `len(x) * eps`, where *eps* is the relative precision of the float type, about 2e-16 in most cases.

full

[bool, optional] Switch determining nature of return value. When it is False (the default) just the coefficients are returned, when True diagnostic information from the singular value decomposition is also returned.

w

[array_like, shape (M,), optional] Weights. If not None, the weight $w[i]$ applies to the unsquared residual $y[i] - \hat{y}[i]$ at $x[i]$. Ideally the weights are chosen so that the errors of the products $w[i]*y[i]$ all have the same variance. When using inverse-variance weighting, use $w[i] = 1/\text{sigma}(y[i])$. The default value is None.

window

[[[beg, end]], optional] Window to use for the returned series. The default value is the default class domain

symbol

[str, optional] Symbol representing the independent variable. Default is 'x'.

Returns**new_series**

[series] A series that represents the least squares fit to the data and has the domain and window specified in the call. If the coefficients for the unscaled and unshifted basis polynomials are of interest, do `new_series.convert().coef`.

[resid, rank, sv, rcond]

[list] These values are only returned if `full == True`

- resid – sum of squared residuals of the least squares fit
- rank – the numerical rank of the scaled Vandermonde matrix
- sv – singular values of the scaled Vandermonde matrix
- rcond – value of *rcond*.

For more details, see [*linalg.lstsq*](#).

method

classmethod `polynomial.hermite.Hermite.fromroots` (*roots*, *domain*=[], *window*=None, *symbol*='x')

Return series instance that has the specified roots.

Returns a series representing the product $(x - r[0]) * (x - r[1]) * \dots * (x - r[n-1])$, where *r* is a list of roots.

Parameters**roots**

[array_like] List of roots.

domain

[[], None, array_like], optional] Domain for the resulting series. If None the domain is the interval from the smallest root to the largest. If [] the domain is the class domain. The default is [].

window

[None, array_like], optional] Window for the returned series. If None the class window is used. The default is None.

symbol

[str, optional] Symbol representing the independent variable. Default is 'x'.

Returns**new_series**

[series] Series with the specified roots.

method

`polynomial.hermite.Hermite.has_samecoef(other)`

Check if coefficients match.

Parameters**other**

[class instance] The other class must have the `coef` attribute.

Returns**bool**

[boolean] True if the coefficients are the same, False otherwise.

method

`polynomial.hermite.Hermite.has_samedomain(other)`

Check if domains match.

Parameters**other**

[class instance] The other class must have the `domain` attribute.

Returns**bool**

[boolean] True if the domains are the same, False otherwise.

method

`polynomial.hermite.Hermite.has_sametype(other)`

Check if types match.

Parameters**other**

[object] Class instance.

Returns**bool**

[boolean] True if other is same class as self

method

`polynomial.hermite.Hermite.has_samewindow(other)`

Check if windows match.

Parameters**other**

[class instance] The other class must have the `window` attribute.

Returns**bool**

[boolean] True if the windows are the same, False otherwise.

method

classmethod `polynomial.hermite.Hermite.identity` (*domain=None, window=None, symbol='x'*)

Identity function.

If p is the returned series, then $p(x) == x$ for all values of x .

Parameters

domain

[*None*, array_like], optional] If given, the array must be of the form [*beg*, *end*], where *beg* and *end* are the endpoints of the domain. If *None* is given then the class domain is used. The default is *None*.

window

[*None*, array_like], optional] If given, the resulting array must be if the form [*beg*, *end*], where *beg* and *end* are the endpoints of the window. If *None* is given then the class window is used. The default is *None*.

symbol

[str, optional] Symbol representing the independent variable. Default is 'x'.

Returns

new_series

[series] Series of representing the identity.

method

`polynomial.hermite.Hermite.integ` (*m=1, k=[], lbnd=None*)

Integrate.

Return a series instance that is the definite integral of the current series.

Parameters

m

[non-negative int] The number of integrations to perform.

k

[array_like] Integration constants. The first constant is applied to the first integration, the second to the second, and so on. The list of values must less than or equal to *m* in length and any missing values are set to zero.

lbnd

[Scalar] The lower bound of the definite integral.

Returns

new_series

[series] A new series representing the integral. The domain is the same as the domain of the integrated series.

method

`polynomial.hermite.Hermite.linspace` (*n=100, domain=None*)

Return x , y values at equally spaced points in domain.

Returns the x , y values at n linearly spaced points across the domain. Here y is the value of the polynomial at the points x . By default the domain is the same as that of the series instance. This method is intended mostly as a plotting aid.

Parameters

n

[int, optional] Number of point pairs to return. The default value is 100.

domain

[{None, array_like}, optional] If not None, the specified domain is used instead of that of the calling instance. It should be of the form `[beg, end]`. The default is None which case the class domain is used.

Returns**x, y**

[ndarray] x is equal to `linspace(self.domain[0], self.domain[1], n)` and y is the series evaluated at element of x.

method

`polynomial.hermite.Hermite.mapparms()`

Return the mapping parameters.

The returned values define a linear map `off + scl*x` that is applied to the input arguments before the series is evaluated. The map depends on the `domain` and `window`; if the current `domain` is equal to the `window` the resulting map is the identity. If the coefficients of the series instance are to be used by themselves outside this class, then the linear function must be substituted for the `x` in the standard representation of the base polynomials.

Returns**off, scl**

[float or complex] The mapping function is defined by `off + scl*x`.

Notes

If the current domain is the interval `[l1, r1]` and the window is `[l2, r2]`, then the linear mapping function `L` is defined by the equations:

$$\begin{aligned}L(l1) &= l2 \\ L(r1) &= r2\end{aligned}$$

method

`polynomial.hermite.Hermite.roots()`

Return the roots of the series polynomial.

Compute the roots for the series. Note that the accuracy of the roots decreases the further outside the domain they lie.

Returns**roots**

[ndarray] Array containing the roots of the series.

method

`polynomial.hermite.Hermite.trim(tol=0)`

Remove trailing coefficients

Remove trailing coefficients until a coefficient is reached whose absolute value greater than `tol` or the beginning of the series is reached. If all the coefficients would be removed the series is set to `[0]`. A new series instance is returned with the new coefficients. The current instance remains unchanged.

Parameters

tol
[non-negative number.] All trailing coefficients less than *tol* will be removed.

Returns

new_series
[series] New instance of series with trimmed coefficients.

method

`polynomial.hermite.Hermite.truncate(size)`

Truncate series to length *size*.

Reduce the series to length *size* by discarding the high degree terms. The value of *size* must be a positive integer. This can be useful in least squares where the coefficients of the high degree terms may be very small.

Parameters

size
[positive int] The series is reduced to length *size* by discarding the high degree terms. The value of *size* must be a positive integer.

Returns

new_series
[series] New instance of series with truncated coefficients.

Constants

<i>hermdomain</i>	<code>ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None)</code>
<i>hermzero</i>	<code>ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None)</code>
<i>hermone</i>	<code>ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None)</code>
<i>hermx</i>	<code>ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None)</code>

`polynomial.hermite.hermdomain = array([-1., 1.])`

`ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None) –`

`ndarray(shape, dtype=np.float64, buffer=None, offset=0, strides=None, order=None)`

An array object represents a multidimensional, homogeneous array of fixed-size items. An associated data-type object describes the format of each element in the array (its byte-order, how many bytes it occupies in memory, whether it is an integer, a floating point number, or something else, etc.)

Arrays should be constructed using *array*, *zeros* or *empty* (refer to the See Also section below). The parameters given here refer to a low-level method (*ndarray(...)*) for instantiating an array.

For more information, refer to the *numpy* module and examine the methods and attributes of an array.

Parameters

(for the `__new__` method; see Notes below)

shape
[tuple of ints] Shape of created array.

dtype

[data-type, optional] Any object that can be interpreted as a numpy data type. Default is `numpy.float64`.

buffer

[object exposing buffer interface, optional] Used to fill the array with data.

offset

[int, optional] Offset of array data in buffer.

strides

[tuple of ints, optional] Strides of data in memory.

order

[{'C', 'F'}, optional] Row-major (C-style) or column-major (Fortran-style) order.

Attributes**T**

[ndarray] Transpose of the array.

data

[buffer] The array's elements, in memory.

dtype

[dtype object] Describes the format of the elements in the array.

flags

[dict] Dictionary containing information related to memory use, e.g., 'C_CONTIGUOUS', 'OWNDATA', 'WRITEABLE', etc.

flat

[numpy.flatiter object] Flattened version of the array as an iterator. The iterator allows assignments, e.g., `x.flat = 3` (See `ndarray.flat` for assignment examples; TODO).

imag

[ndarray] Imaginary part of the array.

real

[ndarray] Real part of the array.

size

[int] Number of elements in the array.

itemsize

[int] The memory use of each array element in bytes.

nbytes

[int] The total number of bytes required to store the array data, i.e., `itemsize * size`.

ndim

[int] The array's number of dimensions.

shape

[tuple of ints] Shape of the array.

strides

[tuple of ints] The step-size required to move from one element to the next in memory. For example, a contiguous (3, 4) array of type `int16` in C-order has strides (8, 2). This implies that to move from element to element in memory requires jumps of 2 bytes. To move from row-to-row, one needs to jump 8 bytes at a time (2 * 4).

ctypes

[ctypes object] Class containing properties of the array needed for interaction with ctypes.

base

[ndarray] If the array is a view into another array, that array is its *base* (unless that array is also a view). The *base* array is where the array data is actually stored.

See also:**array**

Construct an array.

zeros

Create an array, each element of which is zero.

empty

Create an array, but leave its allocated memory unchanged (i.e., it contains “garbage”).

dtype

Create a data-type.

numpy.typing.NDArray

An ndarray alias *generic* w.r.t. its *dtype.type*.

Notes

There are two modes of creating an array using `__new__`:

1. If *buffer* is None, then only *shape*, *dtype*, and *order* are used.
2. If *buffer* is an object exposing the buffer interface, then all keywords are interpreted.

No `__init__` method is needed because the array is fully initialized after the `__new__` method.

Examples

These examples illustrate the low-level *ndarray* constructor. Refer to the *See Also* section above for easier ways of constructing an ndarray.

First mode, *buffer* is None:

```
>>> import numpy as np
>>> np.ndarray(shape=(2,2), dtype=np.float64, order='F')
array([[0.0e+000, 0.0e+000], # random
       [      nan, 2.5e-323]])
```

Second mode:

```
>>> np.ndarray((2,), buffer=np.array([1,2,3]),
...           offset=np.int_().itemsize,
...           dtype=np.int_) # offset = 1*itemsize, i.e. skip first element
array([2, 3])
```

```
polynomial.hermite.hermzero = array([0])
```

```
ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None) –
```

```
ndarray(shape, dtype=np.float64, buffer=None, offset=0, strides=None, order=None)
```

An array object represents a multidimensional, homogeneous array of fixed-size items. An associated data-type object describes the format of each element in the array (its byte-order, how many bytes it occupies in memory, whether it is an integer, a floating point number, or something else, etc.)

Arrays should be constructed using `array`, `zeros` or `empty` (refer to the See Also section below). The parameters given here refer to a low-level method (`ndarray(...)`) for instantiating an array.

For more information, refer to the `numpy` module and examine the methods and attributes of an array.

Parameters

(for the `__new__` method; see Notes below)

shape

[tuple of ints] Shape of created array.

dtype

[data-type, optional] Any object that can be interpreted as a numpy data type. Default is `numpy.float64`.

buffer

[object exposing buffer interface, optional] Used to fill the array with data.

offset

[int, optional] Offset of array data in buffer.

strides

[tuple of ints, optional] Strides of data in memory.

order

[[`'C'`, `'F'`], optional] Row-major (C-style) or column-major (Fortran-style) order.

Attributes

T

[ndarray] Transpose of the array.

data

[buffer] The array's elements, in memory.

dtype

[dtype object] Describes the format of the elements in the array.

flags

[dict] Dictionary containing information related to memory use, e.g., `'C_CONTIGUOUS'`, `'OWNDATA'`, `'WRITEABLE'`, etc.

flat

[numpy.flatiter object] Flattened version of the array as an iterator. The iterator allows assignments, e.g., `x.flat = 3` (See `ndarray.flat` for assignment examples; TODO).

imag

[ndarray] Imaginary part of the array.

real

[ndarray] Real part of the array.

size

[int] Number of elements in the array.

itemsize

[int] The memory use of each array element in bytes.

nbytes

[int] The total number of bytes required to store the array data, i.e., `itemsize * size`.

ndim

[int] The array's number of dimensions.

shape

[tuple of ints] Shape of the array.

strides

[tuple of ints] The step-size required to move from one element to the next in memory. For example, a contiguous (3, 4) array of type `int16` in C-order has strides (8, 2). This implies that to move from element to element in memory requires jumps of 2 bytes. To move from row-to-row, one needs to jump 8 bytes at a time ($2 * 4$).

ctypes

[ctypes object] Class containing properties of the array needed for interaction with ctypes.

base

[ndarray] If the array is a view into another array, that array is its *base* (unless that array is also a view). The *base* array is where the array data is actually stored.

See also:**`array`**

Construct an array.

`zeros`

Create an array, each element of which is zero.

`empty`

Create an array, but leave its allocated memory unchanged (i.e., it contains “garbage”).

`dtype`

Create a data-type.

`numpy.typing.NDArray`

An ndarray alias *generic* w.r.t. its `dtype.type`.

Notes

There are two modes of creating an array using `__new__`:

1. If *buffer* is None, then only *shape*, *dtype*, and *order* are used.
2. If *buffer* is an object exposing the buffer interface, then all keywords are interpreted.

No `__init__` method is needed because the array is fully initialized after the `__new__` method.

Examples

These examples illustrate the low-level *ndarray* constructor. Refer to the *See Also* section above for easier ways of constructing an ndarray.

First mode, *buffer* is None:

```
>>> import numpy as np
>>> np.ndarray(shape=(2,2), dtype=np.float64, order='F')
array([[0.0e+000, 0.0e+000], # random
       [      nan, 2.5e-323]])
```

Second mode:

```
>>> np.ndarray((2,), buffer=np.array([1,2,3]),
...           offset=np.int_().itemsize,
...           dtype=np.int_) # offset = 1*itemsize, i.e. skip first element
array([2, 3])
```

```
polynomial.hermite.hermone = array([1])
```

```
ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None) -
```

```
ndarray(shape, dtype=np.float64, buffer=None, offset=0, strides=None, order=None)
```

An array object represents a multidimensional, homogeneous array of fixed-size items. An associated data-type object describes the format of each element in the array (its byte-order, how many bytes it occupies in memory, whether it is an integer, a floating point number, or something else, etc.)

Arrays should be constructed using *array*, *zeros* or *empty* (refer to the See Also section below). The parameters given here refer to a low-level method (*ndarray(...)*) for instantiating an array.

For more information, refer to the *numpy* module and examine the methods and attributes of an array.

Parameters

(for the `__new__` method; see Notes below)

shape

[tuple of ints] Shape of created array.

dtype

[data-type, optional] Any object that can be interpreted as a numpy data type. Default is *numpy.float64*.

buffer

[object exposing buffer interface, optional] Used to fill the array with data.

offset

[int, optional] Offset of array data in buffer.

strides

[tuple of ints, optional] Strides of data in memory.

order

[{'C', 'F'}, optional] Row-major (C-style) or column-major (Fortran-style) order.

Attributes

T

[ndarray] Transpose of the array.

data

[buffer] The array's elements, in memory.

dtype

[dtype object] Describes the format of the elements in the array.

flags

[dict] Dictionary containing information related to memory use, e.g., 'C_CONTIGUOUS', 'OWNDATA', 'WRITEABLE', etc.

flat

[numpy.flatiter object] Flattened version of the array as an iterator. The iterator allows assignments, e.g., `x.flat = 3` (See *ndarray.flat* for assignment examples; TODO).

imag

[ndarray] Imaginary part of the array.

real

[ndarray] Real part of the array.

size

[int] Number of elements in the array.

itemsize

[int] The memory use of each array element in bytes.

nbytes

[int] The total number of bytes required to store the array data, i.e., `itemsize * size`.

ndim

[int] The array's number of dimensions.

shape

[tuple of ints] Shape of the array.

strides

[tuple of ints] The step-size required to move from one element to the next in memory. For example, a contiguous (3, 4) array of type `int16` in C-order has strides (8, 2). This implies that to move from element to element in memory requires jumps of 2 bytes. To move from row-to-row, one needs to jump 8 bytes at a time (2 * 4).

ctypes

[ctypes object] Class containing properties of the array needed for interaction with ctypes.

base

[ndarray] If the array is a view into another array, that array is its *base* (unless that array is also a view). The *base* array is where the array data is actually stored.

See also:**`array`**

Construct an array.

`zeros`

Create an array, each element of which is zero.

`empty`

Create an array, but leave its allocated memory unchanged (i.e., it contains “garbage”).

`dtype`

Create a data-type.

`numpy.typing.NDArray`

An ndarray alias *generic* w.r.t. its `dtype.type`.

Notes

There are two modes of creating an array using `__new__`:

1. If *buffer* is None, then only *shape*, *dtype*, and *order* are used.
2. If *buffer* is an object exposing the buffer interface, then all keywords are interpreted.

No `__init__` method is needed because the array is fully initialized after the `__new__` method.

Examples

These examples illustrate the low-level `ndarray` constructor. Refer to the *See Also* section above for easier ways of constructing an ndarray.

First mode, *buffer* is None:

```
>>> import numpy as np
>>> np.ndarray(shape=(2,2), dtype=np.float64, order='F')
array([[0.0e+000, 0.0e+000], # random
       [      nan, 2.5e-323]])
```

Second mode:

```
>>> np.ndarray((2,), buffer=np.array([1,2,3]),
...           offset=np.int_().itemsize,
...           dtype=np.int_) # offset = 1*itemsize, i.e. skip first element
array([2, 3])
```

```
polynomial.hermite.hermx = array([0. , 0.5])
```

`ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None) –`

`ndarray(shape, dtype=np.float64, buffer=None, offset=0, strides=None, order=None)`

An array object represents a multidimensional, homogeneous array of fixed-size items. An associated data-type object describes the format of each element in the array (its byte-order, how many bytes it occupies in memory, whether it is an integer, a floating point number, or something else, etc.)

Arrays should be constructed using `array`, `zeros` or `empty` (refer to the *See Also* section below). The parameters given here refer to a low-level method (`ndarray(...)`) for instantiating an array.

For more information, refer to the `numpy` module and examine the methods and attributes of an array.

Parameters

(for the `__new__` method; see Notes below)

shape

[tuple of ints] Shape of created array.

dtype

[data-type, optional] Any object that can be interpreted as a numpy data type. Default is `numpy.float64`.

buffer

[object exposing buffer interface, optional] Used to fill the array with data.

offset

[int, optional] Offset of array data in buffer.

strides

[tuple of ints, optional] Strides of data in memory.

order

[{'C', 'F'}, optional] Row-major (C-style) or column-major (Fortran-style) order.

Attributes

T

[ndarray] Transpose of the array.

data

[buffer] The array's elements, in memory.

dtype

[dtype object] Describes the format of the elements in the array.

flags

[dict] Dictionary containing information related to memory use, e.g., 'C_CONTIGUOUS', 'OWNDATA', 'WRITEABLE', etc.

flat

[numpy.flatiter object] Flattened version of the array as an iterator. The iterator allows assignments, e.g., `x.flat = 3` (See [ndarray.flat](#) for assignment examples; TODO).

imag

[ndarray] Imaginary part of the array.

real

[ndarray] Real part of the array.

size

[int] Number of elements in the array.

itemsize

[int] The memory use of each array element in bytes.

nbytes

[int] The total number of bytes required to store the array data, i.e., `itemsize * size`.

ndim

[int] The array's number of dimensions.

shape

[tuple of ints] Shape of the array.

strides

[tuple of ints] The step-size required to move from one element to the next in memory. For example, a contiguous (3, 4) array of type `int16` in C-order has strides (8, 2). This implies that to move from element to element in memory requires jumps of 2 bytes. To move from row-to-row, one needs to jump 8 bytes at a time (2 * 4).

ctypes

[ctypes object] Class containing properties of the array needed for interaction with ctypes.

base

[ndarray] If the array is a view into another array, that array is its *base* (unless that array is also a view). The *base* array is where the array data is actually stored.

See also:**[array](#)**

Construct an array.

[zeros](#)

Create an array, each element of which is zero.

[empty](#)

Create an array, but leave its allocated memory unchanged (i.e., it contains "garbage").

[dtype](#)

Create a data-type.

[numpy.typing.NDArray](#)

An ndarray alias *generic* w.r.t. its `dtype.type`.

Notes

There are two modes of creating an array using `__new__`:

1. If *buffer* is None, then only *shape*, *dtype*, and *order* are used.
2. If *buffer* is an object exposing the buffer interface, then all keywords are interpreted.

No `__init__` method is needed because the array is fully initialized after the `__new__` method.

Examples

These examples illustrate the low-level *ndarray* constructor. Refer to the *See Also* section above for easier ways of constructing an ndarray.

First mode, *buffer* is None:

```
>>> import numpy as np
>>> np.ndarray(shape=(2,2), dtype=np.float64, order='F')
array([[0.0e+000, 0.0e+000], # random
       [      nan, 2.5e-323]])
```

Second mode:

```
>>> np.ndarray((2,), buffer=np.array([1,2,3]),
...           offset=np.int_().itemsize,
...           dtype=np.int_) # offset = 1*itemsize, i.e. skip first element
array([2, 3])
```

Arithmetic

<i>hermadd</i> (c1, c2)	Add one Hermite series to another.
<i>hermsub</i> (c1, c2)	Subtract one Hermite series from another.
<i>hermmulx</i> (c)	Multiply a Hermite series by x.
<i>hermmul</i> (c1, c2)	Multiply one Hermite series by another.
<i>hermdiv</i> (c1, c2)	Divide one Hermite series by another.
<i>hermpow</i> (c, pow[, maxpower])	Raise a Hermite series to a power.
<i>hermval</i> (x, c[, tensor])	Evaluate a Hermite series at points x.
<i>hermval2d</i> (x, y, c)	Evaluate a 2-D Hermite series at points (x, y).
<i>hermval3d</i> (x, y, z, c)	Evaluate a 3-D Hermite series at points (x, y, z).
<i>hermvalnd</i> (pts, c)	Evaluate an N-D Hermite series at points.
<i>hermgrid2d</i> (x, y, c)	Evaluate a 2-D Hermite series on the Cartesian product of x and y.
<i>hermgrid3d</i> (x, y, z, c)	Evaluate a 3-D Hermite series on the Cartesian product of x, y, and z.

`polynomial.hermite.hermadd(c1, c2)`

Add one Hermite series to another.

Returns the sum of two Hermite series *c1* + *c2*. The arguments are sequences of coefficients ordered from lowest order term to highest, i.e., [1,2,3] represents the series $P_0 + 2P_1 + 3P_2$.

Parameters

c1, c2

[array_like] 1-D arrays of Hermite series coefficients ordered from low to high.

Returns**out**

[ndarray] Array representing the Hermite series of their sum.

See also:*hermsub, hermmulx, hermmul, hermdiv, hermpow***Notes**

Unlike multiplication, division, etc., the sum of two Hermite series is a Hermite series (without having to “reproject” the result onto the basis set) so addition, just like that of “standard” polynomials, is simply “component-wise.”

Examples

```
>>> from numpy.polynomial.hermite import hermadd
>>> hermadd([1, 2, 3], [1, 2, 3, 4])
array([2., 4., 6., 4.]
```

`polynomial.hermite.hermsub(c1, c2)`

Subtract one Hermite series from another.

Returns the difference of two Hermite series $c1 - c2$. The sequences of coefficients are from lowest order term to highest, i.e., [1,2,3] represents the series $P_0 + 2*P_1 + 3*P_2$.

Parameters**c1, c2**

[array_like] 1-D arrays of Hermite series coefficients ordered from low to high.

Returns**out**

[ndarray] Of Hermite series coefficients representing their difference.

See also:*hermadd, hermmulx, hermmul, hermdiv, hermpow***Notes**

Unlike multiplication, division, etc., the difference of two Hermite series is a Hermite series (without having to “reproject” the result onto the basis set) so subtraction, just like that of “standard” polynomials, is simply “component-wise.”

Examples

```
>>> from numpy.polynomial.hermite import hermsub
>>> hermsub([1, 2, 3, 4], [1, 2, 3])
array([0., 0., 0., 4.] )
```

`polynomial.hermite.hermmulx(c)`

Multiply a Hermite series by x .

Multiply the Hermite series c by x , where x is the independent variable.

Parameters

c
[array_like] 1-D array of Hermite series coefficients ordered from low to high.

Returns

out
[ndarray] Array representing the result of the multiplication.

See also:

[*hermadd*](#), [*hermsub*](#), [*hermmul*](#), [*hermdiv*](#), [*hermpow*](#)

Notes

The multiplication uses the recursion relationship for Hermite polynomials in the form

$$xP_i(x) = (P_{i+1}(x)/2 + i * P_{i-1}(x))$$

Examples

```
>>> from numpy.polynomial.hermite import hermmulx
>>> hermmulx([1, 2, 3])
array([2. , 6.5, 1. , 1.5])
```

`polynomial.hermite.hermmul(c1, c2)`

Multiply one Hermite series by another.

Returns the product of two Hermite series $c1 * c2$. The arguments are sequences of coefficients, from lowest order “term” to highest, e.g., [1,2,3] represents the series $P_0 + 2*P_1 + 3*P_2$.

Parameters

c1, c2
[array_like] 1-D arrays of Hermite series coefficients ordered from low to high.

Returns

out
[ndarray] Of Hermite series coefficients representing their product.

See also:

[*hermadd*](#), [*hermsub*](#), [*hermmulx*](#), [*hermdiv*](#), [*hermpow*](#)

Notes

In general, the (polynomial) product of two C-series results in terms that are not in the Hermite polynomial basis set. Thus, to express the product as a Hermite series, it is necessary to “reproject” the product onto said basis set, which may produce “unintuitive” (but correct) results; see Examples section below.

Examples

```
>>> from numpy.polynomial.hermite import hermmul
>>> hermmul([1, 2, 3], [0, 1, 2])
array([52., 29., 52., 7., 6.]
```

`polynomial.hermite.hermdiv(c1, c2)`

Divide one Hermite series by another.

Returns the quotient-with-remainder of two Hermite series $c1 / c2$. The arguments are sequences of coefficients from lowest order “term” to highest, e.g., [1,2,3] represents the series $P_0 + 2*P_1 + 3*P_2$.

Parameters

c1, c2

[array_like] 1-D arrays of Hermite series coefficients ordered from low to high.

Returns

[quo, rem]

[ndarrays] Of Hermite series coefficients representing the quotient and remainder.

See also:

hermadd, hermsub, hermmulx, hermmul, hermpow

Notes

In general, the (polynomial) division of one Hermite series by another results in quotient and remainder terms that are not in the Hermite polynomial basis set. Thus, to express these results as a Hermite series, it is necessary to “reproject” the results onto the Hermite basis set, which may produce “unintuitive” (but correct) results; see Examples section below.

Examples

```
>>> from numpy.polynomial.hermite import hermdiv
>>> hermdiv([ 52., 29., 52., 7., 6.], [0, 1, 2])
(array([1., 2., 3.]), array([0.]))
>>> hermdiv([ 54., 31., 52., 7., 6.], [0, 1, 2])
(array([1., 2., 3.]), array([2., 2.]))
>>> hermdiv([ 53., 30., 52., 7., 6.], [0, 1, 2])
(array([1., 2., 3.]), array([1., 1.]))
```

`polynomial.hermite.herpow(c, pow, maxpower=16)`

Raise a Hermite series to a power.

Returns the Hermite series c raised to the power pow . The argument c is a sequence of coefficients ordered from low to high. i.e., [1,2,3] is the series $P_0 + 2*P_1 + 3*P_2$.

Parameters

- c**
[array_like] 1-D array of Hermite series coefficients ordered from low to high.
- pow**
[integer] Power to which the series will be raised
- maxpower**
[integer, optional] Maximum power allowed. This is mainly to limit growth of the series to unmanageable size. Default is 16

Returns

- coef**
[ndarray] Hermite series of power.

See also:

[*hermadd*](#), [*hermsub*](#), [*hermmulx*](#), [*hermmul*](#), [*hermdiv*](#)

Examples

```
>>> from numpy.polynomial.hermite import hermpow
>>> hermpow([1, 2, 3], 2)
array([81., 52., 82., 12., 9.] )
```

`polynomial.hermite.hermval` (*x*, *c*, *tensor=True*)

Evaluate a Hermite series at points *x*.

If *c* is of length $n + 1$, this function returns the value:

$$p(x) = c_0 * H_0(x) + c_1 * H_1(x) + ... + c_n * H_n(x)$$

The parameter *x* is converted to an array only if it is a tuple or a list, otherwise it is treated as a scalar. In either case, either *x* or its elements must support multiplication and addition both with themselves and with the elements of *c*.

If *c* is a 1-D array, then $p(x)$ will have the same shape as *x*. If *c* is multidimensional, then the shape of the result depends on the value of *tensor*. If *tensor* is true the shape will be $c.shape[1:] + x.shape$. If *tensor* is false the shape will be $c.shape[1:]$. Note that scalars have shape $()$.

Trailing zeros in the coefficients will be used in the evaluation, so they should be avoided if efficiency is a concern.

Parameters

- x**
[array_like, compatible object] If *x* is a list or tuple, it is converted to an ndarray, otherwise it is left unchanged and treated as a scalar. In either case, *x* or its elements must support addition and multiplication with themselves and with the elements of *c*.
- c**
[array_like] Array of coefficients ordered so that the coefficients for terms of degree *n* are contained in $c[n]$. If *c* is multidimensional the remaining indices enumerate multiple polynomials. In the two dimensional case the coefficients may be thought of as stored in the columns of *c*.
- tensor**
[boolean, optional] If True, the shape of the coefficient array is extended with ones on the right, one for each dimension of *x*. Scalars have dimension 0 for this action. The result is that

every column of coefficients in c is evaluated for every element of x . If False, x is broadcast over the columns of c for the evaluation. This keyword is useful when c is multidimensional. The default value is True.

Returns

values

[ndarray, algebra_like] The shape of the return value is described above.

See also:

[*hermval2d*](#), [*hermgrid2d*](#), [*hermval3d*](#), [*hermgrid3d*](#)

Notes

The evaluation uses Clenshaw recursion, aka synthetic division.

Examples

```
>>> from numpy.polynomial.hermite import hermval
>>> coef = [1,2,3]
>>> hermval(1, coef)
11.0
>>> hermval([[1,2],[3,4]], coef)
array([[ 11.,  51.],
       [115., 203.]])
```

`polynomial.hermite.hermval2d(x, y, c)`

Evaluate a 2-D Hermite series at points (x, y).

This function returns the values:

$$p(x, y) = \sum_{i,j} c_{i,j} * H_i(x) * H_j(y)$$

The parameters x and y are converted to arrays only if they are tuples or a lists, otherwise they are treated as a scalars and they must have the same shape after conversion. In either case, either x and y or their elements must support multiplication and addition both with themselves and with the elements of c .

If c is a 1-D array a one is implicitly appended to its shape to make it 2-D. The shape of the result will be $c.shape[2:] + x.shape$.

Parameters

x, y

[array_like, compatible objects] The two dimensional series is evaluated at the points (x, y) , where x and y must have the same shape. If x or y is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and if it isn't an ndarray it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficient of the term of multi-degree i, j is contained in $c[i, j]$. If c has dimension greater than two the remaining indices enumerate multiple sets of coefficients.

Returns

values

[ndarray, compatible object] The values of the two dimensional polynomial at points formed with pairs of corresponding values from x and y .

See also:

[hermval](#), [hermgrid2d](#), [hermval3d](#), [hermgrid3d](#)

Examples

```
>>> from numpy.polynomial.hermite import hermval2d
>>> x = [1, 2]
>>> y = [4, 5]
>>> c = [[1, 2, 3], [4, 5, 6]]
>>> hermval2d(x, y, c)
array([1035., 2883.])
```

`polynomial.hermite.hermval3d(x, y, z, c)`

Evaluate a 3-D Hermite series at points (x, y, z).

This function returns the values:

$$p(x, y, z) = \sum_{i,j,k} c_{i,j,k} * H_i(x) * H_j(y) * H_k(z)$$

The parameters *x*, *y*, and *z* are converted to arrays only if they are tuples or a lists, otherwise they are treated as scalars and they must have the same shape after conversion. In either case, either *x*, *y*, and *z* or their elements must support multiplication and addition both with themselves and with the elements of *c*.

If *c* has fewer than 3 dimensions, ones are implicitly appended to its shape to make it 3-D. The shape of the result will be *c*.shape[3:] + *x*.shape.

Parameters

x, y, z

[array_like, compatible object] The three dimensional series is evaluated at the points (*x*, *y*, *z*), where *x*, *y*, and *z* must have the same shape. If any of *x*, *y*, or *z* is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and if it isn't an ndarray it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficient of the term of multi-degree *i,j,k* is contained in *c*[*i*, *j*, *k*]. If *c* has dimension greater than 3 the remaining indices enumerate multiple sets of coefficients.

Returns

values

[ndarray, compatible object] The values of the multidimensional polynomial on points formed with triples of corresponding values from *x*, *y*, and *z*.

See also:

[hermval](#), [hermval2d](#), [hermgrid2d](#), [hermgrid3d](#)

Examples

```
>>> from numpy.polynomial.hermite import hermval3d
>>> x = [1, 2]
>>> y = [4, 5]
>>> z = [6, 7]
>>> c = [[[1, 2, 3], [4, 5, 6]], [[7, 8, 9], [10, 11, 12]]]
>>> hermval3d(x, y, z, c)
array([ 40077., 120131.] )
```

`polynomial.hermite.hermvalnd`(*pts*, *c*)

Evaluate an N-D Hermite series at points.

This function returns the values:

$$p(\text{pts}, c) = \sum_{i_1, i_2, \dots, i_n} c_{i_1, i_2, \dots, i_n} * H_{i_1}(x_1) * H_{i_2}(x_2) \dots H_{i_n}(x_n)$$

where $x_1, x_2, \dots, x_n = \text{pts}$. Note that *pts* may also be an (*n*, *m*) array.

The parameters in *pts* are converted to arrays only if they are tuples or lists, otherwise they are treated as scalars and they must have the same shape after conversion. In either case, either the elements of *pts* or their elements must support multiplication and addition both with themselves and with the elements of *c*.

If *c* has fewer than N dimensions, ones are implicitly appended to its shape to make it N-D. The shape of the result will be *c*.shape[N:] + *pts*[0].shape.

Parameters

pts

[tuple or list of array_like, compatible objects] The N-dimensional series is evaluated at the points (*x*₁, *x*₂, ..., *x*_n) provided in the *pts* iterable, where all elements must have the same shape. If any element is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and if it isn't an ndarray it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficient of the term of multi-degree *i*, *j*, *k*, ... is contained in *c*[*i*, *j*, *k*, ...]. If *c* has dimension greater than N, the remaining indices enumerate multiple sets of coefficients.

Returns

values

[ndarray, compatible object] The values of the multidimensional polynomial on points formed with N-tuples of corresponding values from *pts*.

See also:

[`hermval`](#), [`hermval2d`](#), [`hermval3d`](#)

`polynomial.hermite.hermgrid2d`(*x*, *y*, *c*)

Evaluate a 2-D Hermite series on the Cartesian product of *x* and *y*.

This function returns the values:

$$p(a, b) = \sum_{i,j} c_{i,j} * H_i(a) * H_j(b)$$

where the points (*a*, *b*) consist of all pairs formed by taking *a* from *x* and *b* from *y*. The resulting points form a grid with *x* in the first dimension and *y* in the second.

The parameters x and y are converted to arrays only if they are tuples or a lists, otherwise they are treated as a scalars. In either case, either x and y or their elements must support multiplication and addition both with themselves and with the elements of c .

If c has fewer than two dimensions, ones are implicitly appended to its shape to make it 2-D. The shape of the result will be $c.shape[2:] + x.shape$.

Parameters

x, y

[array_like, compatible objects] The two dimensional series is evaluated at the points in the Cartesian product of x and y . If x or y is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and, if it isn't an ndarray, it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficients for terms of degree i, j are contained in $c[i, j]$. If c has dimension greater than two the remaining indices enumerate multiple sets of coefficients.

Returns

values

[ndarray, compatible object] The values of the two dimensional polynomial at points in the Cartesian product of x and y .

See also:

[*hermval*](#), [*hermval2d*](#), [*hermval3d*](#), [*hermgrid3d*](#)

Examples

```
>>> from numpy.polynomial.hermite import hermgrid2d
>>> x = [1, 2, 3]
>>> y = [4, 5]
>>> c = [[1, 2, 3], [4, 5, 6]]
>>> hermgrid2d(x, y, c)
array([[1035., 1599.],
       [1867., 2883.],
       [2699., 4167.]])
```

`polynomial.hermite.hermgrid3d(x, y, z, c)`

Evaluate a 3-D Hermite series on the Cartesian product of x , y , and z .

This function returns the values:

$$p(a, b, c) = \sum_{i,j,k} c_{i,j,k} * H_i(a) * H_j(b) * H_k(c)$$

where the points (a, b, c) consist of all triples formed by taking a from x , b from y , and c from z . The resulting points form a grid with x in the first dimension, y in the second, and z in the third.

The parameters x , y , and z are converted to arrays only if they are tuples or a lists, otherwise they are treated as a scalars. In either case, either x , y , and z or their elements must support multiplication and addition both with themselves and with the elements of c .

If c has fewer than three dimensions, ones are implicitly appended to its shape to make it 3-D. The shape of the result will be $c.shape[3:] + x.shape + y.shape + z.shape$.

Parameters

x, y, z

[array_like, compatible objects] The three dimensional series is evaluated at the points in the Cartesian product of x , y , and z . If x , y , or z is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and, if it isn't an ndarray, it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficients for terms of degree i,j are contained in $c[i, j]$. If c has dimension greater than two the remaining indices enumerate multiple sets of coefficients.

Returns**values**

[ndarray, compatible object] The values of the two dimensional polynomial at points in the Cartesian product of x and y .

Examples

```
>>> from numpy.polynomial.hermite import hermgrid3d
>>> x = [1, 2]
>>> y = [4, 5]
>>> z = [6, 7]
>>> c = [[[1, 2, 3], [4, 5, 6]], [[7, 8, 9], [10, 11, 12]]]
>>> hermgrid3d(x, y, z, c)
array([[[ 40077.,  54117.],
        [ 49293.,  66561.]],
       [[ 72375.,  97719.],
        [ 88975., 120131.]])
```

Calculus

<code>hermdcr(c[, m, scl, axis])</code>	Differentiate a Hermite series.
<code>hermint(c[, m, k, lbnd, scl, axis])</code>	Integrate a Hermite series.

`polynomial.hermite.hermder(c, m=1, scl=1, axis=0)`

Differentiate a Hermite series.

Returns the Hermite series coefficients c differentiated m times along $axis$. At each iteration the result is multiplied by scl (the scaling factor is for use in a linear change of variable). The argument c is an array of coefficients from low to high degree along each axis, e.g., $[1,2,3]$ represents the series $1 \cdot H_0 + 2 \cdot H_1 + 3 \cdot H_2$ while $[[1,2],[1,2]]$ represents $1 \cdot H_0(x) \cdot H_0(y) + 1 \cdot H_1(x) \cdot H_0(y) + 2 \cdot H_0(x) \cdot H_1(y) + 2 \cdot H_1(x) \cdot H_1(y)$ if $axis=0$ is x and $axis=1$ is y .

Parameters**c**

[array_like] Array of Hermite series coefficients. If c is multidimensional the different axis correspond to different variables with the degree in each axis given by the corresponding index.

m

[int, optional] Number of derivatives taken, must be non-negative. (Default: 1)

scl

[scalar, optional] Each differentiation is multiplied by *scl*. The end result is multiplication by *scl***m*. This is for use in a linear change of variable. (Default: 1)

axis

[int, optional] Axis over which the derivative is taken. (Default: 0).

Returns**der**

[ndarray] Hermite series of the derivative.

See also:[*hermint*](#)**Notes**

In general, the result of differentiating a Hermite series does not resemble the same operation on a power series. Thus the result of this function may be “unintuitive,” albeit correct; see Examples section below.

Examples

```
>>> from numpy.polynomial.hermite import hermdr
>>> hermdr([ 1. , 0.5, 0.5, 0.5])
array([1., 2., 3.])
>>> hermdr([-0.5, 1./2., 1./8., 1./12., 1./16.], m=2)
array([1., 2., 3.])
```

`polynomial.hermite.hermint` (*c*, *m*=1, *k*=[], *lbnd*=0, *scl*=1, *axis*=0)

Integrate a Hermite series.

Returns the Hermite series coefficients *c* integrated *m* times from *lbnd* along *axis*. At each iteration the resulting series is **multiplied** by *scl* and an integration constant, *k*, is added. The scaling factor is for use in a linear change of variable. (“Buyer beware”: note that, depending on what one is doing, one may want *scl* to be the reciprocal of what one might expect; for more information, see the Notes section below.) The argument *c* is an array of coefficients from low to high degree along each axis, e.g., [1,2,3] represents the series $H_0 + 2*H_1 + 3*H_2$ while [[1,2],[1,2]] represents $1*H_0(x)*H_0(y) + 1*H_1(x)*H_0(y) + 2*H_0(x)*H_1(y) + 2*H_1(x)*H_1(y)$ if *axis*=0 is *x* and *axis*=1 is *y*.

Parameters**c**

[array_like] Array of Hermite series coefficients. If *c* is multidimensional the different axis correspond to different variables with the degree in each axis given by the corresponding index.

m

[int, optional] Order of integration, must be positive. (Default: 1)

k

[[], list, scalar], optional] Integration constant(s). The value of the first integral at *lbnd* is the first value in the list, the value of the second integral at *lbnd* is the second value, etc. If *k* == [] (the default), all constants are set to zero. If *m* == 1, a single scalar can be given instead of a list.

lbnd

[scalar, optional] The lower bound of the integral. (Default: 0)

scl

[scalar, optional] Following each integration the result is *multiplied* by *scl* before the integration constant is added. (Default: 1)

axis

[int, optional] Axis over which the integral is taken. (Default: 0).

Returns**S**

[ndarray] Hermite series coefficients of the integral.

Raises**ValueError**

If $m < 0$, $\text{len}(k) > m$, $\text{np.ndim}(\text{lbnd}) \neq 0$, or $\text{np.ndim}(\text{scl}) \neq 0$.

See also:[*hermder*](#)**Notes**

Note that the result of each integration is *multiplied* by *scl*. Why is this important to note? Say one is making a linear change of variable $u = ax + b$ in an integral relative to x . Then $dx = du/a$, so one will need to set *scl* equal to $1/a$ - perhaps not what one would have first thought.

Also note that, in general, the result of integrating a C-series needs to be “reprojected” onto the C-series basis set. Thus, typically, the result of this function is “unintuitive,” albeit correct; see Examples section below.

Examples

```
>>> from numpy.polynomial.hermite import hermint
>>> hermint([1,2,3]) # integrate once, value 0 at 0.
array([1. , 0.5, 0.5, 0.5])
>>> hermint([1,2,3], m=2) # integrate twice, value & deriv 0 at 0
array([-0.5      ,  0.5      ,  0.125      ,  0.08333333,  0.0625      ]) # may
↪ vary
>>> hermint([1,2,3], k=1) # integrate once, value 1 at 0.
array([2. , 0.5, 0.5, 0.5])
>>> hermint([1,2,3], lbnd=-1) # integrate once, value 0 at -1
array([-2. ,  0.5,  0.5,  0.5])
>>> hermint([1,2,3], m=2, k=[1,2], lbnd=-1)
array([ 1.66666667, -0.5      ,  0.125      ,  0.08333333,  0.0625      ]) # may
↪ vary
```

Misc Functions

<code>hermfromroots</code> (roots)	Generate a Hermite series with given roots.
<code>hermroots</code> (c)	Compute the roots of a Hermite series.
<code>hermvander</code> (x, deg)	Pseudo-Vandermonde matrix of given degree.
<code>hermvander2d</code> (x, y, deg)	Pseudo-Vandermonde matrix of given degrees.
<code>hermvander3d</code> (x, y, z, deg)	Pseudo-Vandermonde matrix of given degrees.
<code>hermgauss</code> (deg)	Gauss-Hermite quadrature.
<code>hermweight</code> (x)	Weight function of the Hermite polynomials.
<code>hermcompanion</code> (c)	Return the scaled companion matrix of c.
<code>hermfit</code> (x, y, deg[, rcond, full, w])	Least squares fit of Hermite series to data.
<code>hermtrim</code> (c[, tol])	Remove "small" "trailing" coefficients from a polynomial.
<code>hermline</code> (off, scl)	Hermite series whose graph is a straight line.
<code>herm2poly</code> (c)	Convert a Hermite series to a polynomial.
<code>poly2herm</code> (pol)	Convert a polynomial to a Hermite series.

`polynomial.hermite.hermfromroots` (roots)

Generate a Hermite series with given roots.

The function returns the coefficients of the polynomial

$$p(x) = (x - r_0) * (x - r_1) * \dots * (x - r_n),$$

in Hermite form, where the r_n are the roots specified in `roots`. If a zero has multiplicity n , then it must appear in `roots` n times. For instance, if 2 is a root of multiplicity three and 3 is a root of multiplicity 2, then `roots` looks something like [2, 2, 2, 3, 3]. The roots can appear in any order.

If the returned coefficients are c , then

$$p(x) = c_0 + c_1 * H_1(x) + \dots + c_n * H_n(x)$$

The coefficient of the last term is not generally 1 for monic polynomials in Hermite form.

Parameters

roots

[array_like] Sequence containing the roots.

Returns

out

[ndarray] 1-D array of coefficients. If all roots are real then `out` is a real array, if some of the roots are complex, then `out` is complex even if all the coefficients in the result are real (see Examples below).

See also:

`numpy.polynomial.polynomial.polyfromroots`
`numpy.polynomial.legendre.legfromroots`
`numpy.polynomial.laguerre.lagfromroots`
`numpy.polynomial.chebyshev.chebfromroots`
`numpy.polynomial.hermite_e.hermefromroots`

Examples

```
>>> from numpy.polynomial.hermite import hermfromroots, hermval
>>> coef = hermfromroots((-1, 0, 1))
>>> hermval((-1, 0, 1), coef)
array([0., 0., 0.])
>>> coef = hermfromroots((-1j, 1j))
>>> hermval((-1j, 1j), coef)
array([0.+0.j, 0.+0.j])
```

`polynomial.hermite.hermroots(c)`

Compute the roots of a Hermite series.

Return the roots (a.k.a. “zeros”) of the polynomial

$$p(x) = \sum_i c[i] * H_i(x).$$

Parameters

c
[1-D array_like] 1-D array of coefficients.

Returns

out
[ndarray] Array of the roots of the series. If all the roots are real, then *out* is also real, otherwise it is complex.

See also:

numpy.polynomial.polynomial.polyroots
numpy.polynomial.legendre.legroots
numpy.polynomial.laguerre.lagroots
numpy.polynomial.chebyshev.chebroots
numpy.polynomial.hermite_e.hermeroots

Notes

The root estimates are obtained as the eigenvalues of the companion matrix, Roots far from the origin of the complex plane may have large errors due to the numerical instability of the series for such values. Roots with multiplicity greater than 1 will also show larger errors as the value of the series near such points is relatively insensitive to errors in the roots. Isolated roots near the origin can be improved by a few iterations of Newton’s method.

The Hermite series basis polynomials aren’t powers of x so the results of this function may seem unintuitive.

Examples

```
>>> from numpy.polynomial.hermite import hermroots, hermfromroots
>>> coef = hermfromroots([-1, 0, 1])
>>> coef
array([0.    ,  0.25 ,  0.    ,  0.125])
>>> hermroots(coef)
array([-1.00000000e+00, -1.38777878e-17,  1.00000000e+00])
```

`polynomial.hermite.hermvander(x, deg)`

Pseudo-Vandermonde matrix of given degree.

Returns the pseudo-Vandermonde matrix of degree *deg* and sample points *x*. The pseudo-Vandermonde matrix is defined by

$$V[... , i] = H_i(x),$$

where $0 \leq i \leq \text{deg}$. The leading indices of *V* index the elements of *x* and the last index is the degree of the Hermite polynomial.

If *c* is a 1-D array of coefficients of length $n + 1$ and *V* is the array $V = \text{hermvander}(x, n)$, then `np.dot(V, c)` and `hermval(x, c)` are the same up to roundoff. This equivalence is useful both for least squares fitting and for the evaluation of a large number of Hermite series of the same degree and sample points.

Parameters

x

[array_like] Array of points. The dtype is converted to float64 or complex128 depending on whether any of the elements are complex. If *x* is scalar it is converted to a 1-D array.

deg

[int] Degree of the resulting matrix.

Returns

vander

[ndarray] The pseudo-Vandermonde matrix. The shape of the returned matrix is `x.shape + (deg + 1,)`, where The last index is the degree of the corresponding Hermite polynomial. The dtype will be the same as the converted *x*.

Examples

```
>>> import numpy as np
>>> from numpy.polynomial.hermite import hermvander
>>> x = np.array([-1, 0, 1])
>>> hermvander(x, 3)
array([[ 1., -2.,  2.,  4.],
       [ 1.,  0., -2., -0.],
       [ 1.,  2.,  2., -4.]])
```

`polynomial.hermite.hermvander2d(x, y, deg)`

Pseudo-Vandermonde matrix of given degrees.

Returns the pseudo-Vandermonde matrix of degrees *deg* and sample points (*x*, *y*). The pseudo-Vandermonde matrix is defined by

$$V[... , (\text{deg}[1] + 1) * i + j] = H_i(x) * H_j(y),$$

where $0 \leq i \leq \text{deg}[0]$ and $0 \leq j \leq \text{deg}[1]$. The leading indices of V index the points (x, y) and the last index encodes the degrees of the Hermite polynomials.

If $V = \text{hermvander2d}(x, y, [\text{xdeg}, \text{ydeg}])$, then the columns of V correspond to the elements of a 2-D coefficient array c of shape $(\text{xdeg} + 1, \text{ydeg} + 1)$ in the order

$$c_{00}, c_{01}, c_{02}, \dots, c_{10}, c_{11}, c_{12}, \dots$$

and $\text{np.dot}(V, c.\text{flat})$ and $\text{hermval2d}(x, y, c)$ will be the same up to roundoff. This equivalence is useful both for least squares fitting and for the evaluation of a large number of 2-D Hermite series of the same degrees and sample points.

Parameters

x, y

[array_like] Arrays of point coordinates, all of the same shape. The dtypes will be converted to either float64 or complex128 depending on whether any of the elements are complex. Scalars are converted to 1-D arrays.

deg

[list of ints] List of maximum degrees of the form $[x_deg, y_deg]$.

Returns

vander2d

[ndarray] The shape of the returned matrix is $x.\text{shape} + (\text{order},)$, where $\text{order} = (\text{deg}[0] + 1) * (\text{deg}[1] + 1)$. The dtype will be the same as the converted x and y .

See also:

[*hermvander*](#), [*hermvander3d*](#), [*hermval2d*](#), [*hermval3d*](#)

Examples

```
>>> import numpy as np
>>> from numpy.polynomial.hermite import hermivander2d
>>> x = np.array([-1, 0, 1])
>>> y = np.array([-1, 0, 1])
>>> hermivander2d(x, y, [2, 2])
array([[ 1., -2.,  2., -2.,  4., -4.,  2., -4.,  4.],
       [ 1.,  0., -2.,  0.,  0., -0., -2., -0.,  4.],
       [ 1.,  2.,  2.,  2.,  4.,  4.,  2.,  4.,  4.]])
```

`polynomial.hermite.hermivander3d(x, y, z, deg)`

Pseudo-Vandermonde matrix of given degrees.

Returns the pseudo-Vandermonde matrix of degrees deg and sample points (x, y, z) . If l, m, n are the given degrees in x, y, z , then The pseudo-Vandermonde matrix is defined by

$$V[\dots, (m+1)(n+1)i + (n+1)j + k] = H_i(x) * H_j(y) * H_k(z),$$

where $0 \leq i \leq l, 0 \leq j \leq m$, and $0 \leq k \leq n$. The leading indices of V index the points (x, y, z) and the last index encodes the degrees of the Hermite polynomials.

If $V = \text{hermvander3d}(x, y, z, [\text{xdeg}, \text{ydeg}, \text{zdeg}])$, then the columns of V correspond to the elements of a 3-D coefficient array c of shape $(\text{xdeg} + 1, \text{ydeg} + 1, \text{zdeg} + 1)$ in the order

$$c_{000}, c_{001}, c_{002}, \dots, c_{010}, c_{011}, c_{012}, \dots$$

and `np.dot(V, c.flat)` and `hermval3d(x, y, z, c)` will be the same up to roundoff. This equivalence is useful both for least squares fitting and for the evaluation of a large number of 3-D Hermite series of the same degrees and sample points.

Parameters

x, y, z

[array_like] Arrays of point coordinates, all of the same shape. The dtypes will be converted to either float64 or complex128 depending on whether any of the elements are complex. Scalars are converted to 1-D arrays.

deg

[list of ints] List of maximum degrees of the form `[x_deg, y_deg, z_deg]`.

Returns

vander3d

[ndarray] The shape of the returned matrix is `x.shape + (order,)`, where `order = (deg[0] + 1) * (deg[1] + 1) * (deg[2] + 1)`. The dtype will be the same as the converted `x`, `y`, and `z`.

See also:

[*hermvander*](#), [*hermvander3d*](#), [*hermval2d*](#), [*hermval3d*](#)

Examples

```
>>> from numpy.polynomial.hermite import hermivander3d
>>> x = np.array([-1, 0, 1])
>>> y = np.array([-1, 0, 1])
>>> z = np.array([-1, 0, 1])
>>> hermivander3d(x, y, z, [0, 1, 2])
array([[ 1., -2.,  2., -2.,  4., -4.],
       [ 1.,  0., -2.,  0.,  0., -0.],
       [ 1.,  2.,  2.,  2.,  4.,  4.]])
```

`polynomial.hermite.hermgauss(deg)`

Gauss-Hermite quadrature.

Computes the sample points and weights for Gauss-Hermite quadrature. These sample points and weights will correctly integrate polynomials of degree $2 * deg - 1$ or less over the interval $[-\infty, \infty]$ with the weight function $f(x) = \exp(-x^2)$.

Parameters

deg

[int] Number of sample points and weights. It must be ≥ 1 .

Returns

x

[ndarray] 1-D ndarray containing the sample points.

y

[ndarray] 1-D ndarray containing the weights.

Notes

The results have only been tested up to degree 100, higher degrees may be problematic. The weights are determined by using the fact that

$$w_k = c / (H'_n(x_k) * H_{n-1}(x_k))$$

where c is a constant independent of k and x_k is the k 'th root of H_n , and then scaling the results to get the right value when integrating 1.

Examples

```
>>> from numpy.polynomial.hermite import hermgauss
>>> hermgauss(2)
(array([-0.70710678,  0.70710678]), array([0.88622693, 0.88622693]))
```

`polynomial.hermite.hermweight(x)`

Weight function of the Hermite polynomials.

The weight function is $\exp(-x^2)$ and the interval of integration is $[-\infty, \infty]$. the Hermite polynomials are orthogonal, but not normalized, with respect to this weight function.

Parameters

x
[array_like] Values at which the weight function will be computed.

Returns

w
[ndarray] The weight function at x .

Examples

```
>>> import numpy as np
>>> from numpy.polynomial.hermite import hermweight
>>> x = np.arange(-2, 2)
>>> hermweight(x)
array([0.01831564, 0.36787944, 1.          , 0.36787944])
```

`polynomial.hermite.hermcompanion(c)`

Return the scaled companion matrix of c .

The basis polynomials are scaled so that the companion matrix is symmetric when c is a Hermite basis polynomial. This provides better eigenvalue estimates than the unscaled case and for basis polynomials the eigenvalues are guaranteed to be real if `numpy.linalg.eigvalsh` is used to obtain them.

Parameters

c
[array_like] 1-D array of Hermite series coefficients ordered from low to high degree.

Returns

mat
[ndarray] Scaled companion matrix of dimensions (deg, deg).

Examples

```
>>> from numpy.polynomial.hermite import hermcompanion
>>> hermcompanion([1, 0, 1])
array([[0.          , 0.35355339],
       [0.70710678, 0.          ]])
```

`polynomial.hermite.hermfit(x, y, deg, rcond=None, full=False, w=None)`

Least squares fit of Hermite series to data.

Return the coefficients of a Hermite series of degree *deg* that is the least squares fit to the data values *y* given at points *x*. If *y* is 1-D the returned coefficients will also be 1-D. If *y* is 2-D multiple fits are done, one for each column of *y*, and the resulting coefficients are stored in the corresponding columns of a 2-D return. The fitted polynomial(s) are in the form

$$p(x) = c_0 + c_1 * H_1(x) + \dots + c_n * H_n(x),$$

where *n* is *deg*.

Parameters

x

[array_like, shape (M,)] x-coordinates of the M sample points (*x*[*i*], *y*[*i*]).

y

[array_like, shape (M,) or (M, K)] y-coordinates of the sample points. Several data sets of sample points sharing the same x-coordinates can be fitted at once by passing in a 2D-array that contains one dataset per column.

deg

[int or 1-D array_like] Degree(s) of the fitting polynomials. If *deg* is a single integer all terms up to and including the *deg*'th term are included in the fit. For NumPy versions >= 1.11.0 a list of integers specifying the degrees of the terms to include may be used instead.

rcond

[float, optional] Relative condition number of the fit. Singular values smaller than this relative to the largest singular value will be ignored. The default value is `len(x)*eps`, where `eps` is the relative precision of the float type, about 2e-16 in most cases.

full

[bool, optional] Switch determining nature of return value. When it is False (the default) just the coefficients are returned, when True diagnostic information from the singular value decomposition is also returned.

w

[array_like, shape (M,), optional] Weights. If not None, the weight *w*[*i*] applies to the unsquared residual *y*[*i*] - *y*_hat[*i*] at *x*[*i*]. Ideally the weights are chosen so that the errors of the products *w*[*i*]**y*[*i*] all have the same variance. When using inverse-variance weighting, use *w*[*i*] = 1/sigma(*y*[*i*]). The default value is None.

Returns

coef

[ndarray, shape (M,) or (M, K)] Hermite coefficients ordered from low to high. If *y* was 2-D, the coefficients for the data in column *k* of *y* are in column *k*.

[residuals, rank, singular_values, rcond]

[list] These values are only returned if `full == True`

- residuals – sum of squared residuals of the least squares fit

- `rank` – the numerical rank of the scaled Vandermonde matrix
- `singular_values` – singular values of the scaled Vandermonde matrix
- `rcond` – value of `rcond`.

For more details, see `numpy.linalg.lstsq`.

Warns

RankWarning

The rank of the coefficient matrix in the least-squares fit is deficient. The warning is only raised if `full == False`. The warnings can be turned off by

```
>>> import warnings
>>> warnings.simplefilter('ignore', np.exceptions.RankWarning)
```

`numpy.polynomial.laguerre.lagfit`
`numpy.polynomial.polynomial.polyfit`
`numpy.polynomial.hermite_e.hermefit`
`hermval`

Evaluates a Hermite series.

`hermvander`

Vandermonde matrix of Hermite series.

`hermweight`

Hermite weight function

`numpy.linalg.lstsq`

Computes a least-squares fit from the matrix.

`scipy.interpolate.UnivariateSpline`

Computes spline fits.

Notes

The solution is the coefficients of the Hermite series p that minimizes the sum of the weighted squared errors

$$E = \sum_j w_j^2 |y_j - p(x_j)|^2,$$

where the w_j are the weights. This problem is solved by setting up the (typically) overdetermined matrix equation

$$V(x) * c = w * y,$$

where V is the weighted pseudo Vandermonde matrix of x , c are the coefficients to be solved for, w are the weights, y are the observed values. This equation is then solved using the singular value decomposition of V .

If some of the singular values of V are so small that they are neglected, then a `RankWarning` will be issued. This means that the coefficient values may be poorly determined. Using a lower order fit will usually get rid of the warning. The `rcond` parameter can also be set to a value smaller than its default, but the resulting fit may be spurious and have large contributions from roundoff error.

Fits using Hermite series are probably most useful when the data can be approximated by $\sqrt{w(x)} * p(x)$, where $w(x)$ is the Hermite weight. In that case the weight $\sqrt{w(x[i])}$ should be used together with data values $y[i]/\sqrt{w(x[i])}$. The weight function is available as `hermweight`.

Examples

```
>>> import numpy as np
>>> from numpy.polynomial.hermite import hermfit, hermval
>>> x = np.linspace(-10, 10)
>>> rng = np.random.default_rng()
>>> err = rng.normal(scale=1./10, size=len(x))
>>> y = hermval(x, [1, 2, 3]) + err
>>> hermfit(x, y, 2)
array([1.02294967, 2.00016403, 2.99994614]) # may vary
```

`polynomial.hermite.hermtrim(c, tol=0)`

Remove “small” “trailing” coefficients from a polynomial.

“Small” means “small in absolute value” and is controlled by the parameter *tol*; “trailing” means highest order coefficient(s), e.g., in $[0, 1, 1, 0, 0]$ (which represents $0 + x + x^2 + 0x^3 + 0x^4$) both the 3-rd and 4-th order coefficients would be “trimmed.”

Parameters

c

[array_like] 1-d array of coefficients, ordered from lowest order to highest.

tol

[number, optional] Trailing (i.e., highest order) elements with absolute value less than or equal to *tol* (default value is zero) are removed.

Returns

trimmed

[ndarray] 1-d array with trailing zeros removed. If the resulting series would be empty, a series containing a single zero is returned.

Raises

ValueError

If *tol* < 0

Examples

```
>>> from numpy.polynomial import polyutils as pu
>>> pu.trimcoef((0,0,3,0,5,0,0))
array([0., 0., 3., 0., 5.])
>>> pu.trimcoef((0,0,1e-3,0,1e-5,0,0),1e-3) # item == tol is trimmed
array([0.])
>>> i = complex(0,1) # works for complex
>>> pu.trimcoef((3e-4,1e-3*(1-i),5e-4,2e-5*(1+i)), 1e-3)
array([0.0003+0.j, 0.001 -0.001j])
```

`polynomial.hermite.hermline(off, scl)`

Hermite series whose graph is a straight line.

Parameters

off, scl[scalars] The specified line is given by $\text{off} + \text{scl} * x$.**Returns****y**[ndarray] This module's representation of the Hermite series for $\text{off} + \text{scl} * x$.**See also:**

[`numpy.polynomial.polynomial.polyline`](#)
[`numpy.polynomial.chebyshev.chebline`](#)
[`numpy.polynomial.legendre.legline`](#)
[`numpy.polynomial.laguerre.lagline`](#)
[`numpy.polynomial.hermite\_e.hermeline`](#)

Examples

```

>>> from numpy.polynomial.hermite import hermline, hermval
>>> hermval(0,hermline(3, 2))
3.0
>>> hermval(1,hermline(3, 2))
5.0

```

`polynomial.hermite.herm2poly(c)`

Convert a Hermite series to a polynomial.

Convert an array representing the coefficients of a Hermite series, ordered from lowest degree to highest, to an array of the coefficients of the equivalent polynomial (relative to the “standard” basis) ordered from lowest to highest degree.

Parameters**c**

[array_like] 1-D array containing the Hermite series coefficients, ordered from lowest order term to highest.

Returns**pol**

[ndarray] 1-D array containing the coefficients of the equivalent polynomial (relative to the “standard” basis) ordered from lowest order term to highest.

See also:[`poly2herm`](#)

Notes

The easy way to do conversions between polynomial basis sets is to use the convert method of a class instance.

Examples

```
>>> from numpy.polynomial.hermite import herm2poly
>>> herm2poly([ 1. , 2.75 , 0.5 , 0.375])
array([0., 1., 2., 3.] )
```

`polynomial.hermite.poly2herm(pol)`

Convert a polynomial to a Hermite series.

Convert an array representing the coefficients of a polynomial (relative to the “standard” basis) ordered from lowest degree to highest, to an array of the coefficients of the equivalent Hermite series, ordered from lowest to highest degree.

Parameters

pol

[array_like] 1-D array containing the polynomial coefficients

Returns

c

[ndarray] 1-D array containing the coefficients of the equivalent Hermite series.

See also:

herm2poly

Notes

The easy way to do conversions between polynomial basis sets is to use the convert method of a class instance.

Examples

```
>>> from numpy.polynomial.hermite import poly2herm
>>> poly2herm(np.arange(4))
array([1. , 2.75 , 0.5 , 0.375])
```

See also

numpy.polynomial

HermiteE Series, “Probabilists” (`numpy.polynomial.hermite_e`)

This module provides a number of objects (mostly functions) useful for dealing with Hermite_e series, including a *HermiteE* class that encapsulates the usual arithmetic operations. (General information on how this module represents and works with such polynomials is in the docstring for its “parent” sub-package, `numpy.polynomial`).

Classes*HermiteE*(coef[, domain, window, symbol])

A HermiteE series class.

class `numpy.polynomial.hermite_e.HermiteE` (coef, domain=None, window=None, symbol='x')

A HermiteE series class.

The HermiteE class provides the standard Python numerical methods '+', '-', '*', '/', '%', 'divmod', '**', and '()' as well as the attributes and methods listed below.

Parameters**coef**

[array_like] HermiteE coefficients in order of increasing degree, i.e. (1, 2, 3) gives $1*He_0(x) + 2*He_1(x) + 3*He_2(x)$.

domain

[(2,) array_like, optional] Domain to use. The interval [domain[0], domain[1]] is mapped to the interval [window[0], window[1]] by shifting and scaling. The default value is [-1., 1.].

window

[(2,) array_like, optional] Window, see domain for its use. The default value is [-1., 1.].

symbol

[str, optional] Symbol used to represent the independent variable in string representations of the polynomial expression, e.g. for printing. The symbol must be a valid Python identifier. Default value is 'x'.

New in version 1.24.

Attributes**symbol**

Methods

<code>__call__(arg)</code>	Call self as a function.
<code>basis(deg[, domain, window, symbol])</code>	Series basis polynomial of degree <i>deg</i> .
<code>cast(series[, domain, window])</code>	Convert series to series of this class.
<code>convert([domain, kind, window])</code>	Convert series to a different kind and/or domain and/or window.
<code>copy()</code>	Return a copy.
<code>cutdeg(deg)</code>	Truncate series to the given degree.
<code>degree()</code>	The degree of the series.
<code>deriv([m])</code>	Differentiate.
<code>fit(x, y, deg[, domain, rcond, full, w, ...])</code>	Least squares fit to data.
<code>fromroots(roots[, domain, window, symbol])</code>	Return series instance that has the specified roots.
<code>has_samecoef(other)</code>	Check if coefficients match.
<code>has_samedomain(other)</code>	Check if domains match.
<code>has_sametype(other)</code>	Check if types match.
<code>has_samewindow(other)</code>	Check if windows match.
<code>identity([domain, window, symbol])</code>	Identity function.
<code>integ([m, k, lbnd])</code>	Integrate.
<code>linspace([n, domain])</code>	Return x, y values at equally spaced points in domain.
<code>mapparms()</code>	Return the mapping parameters.
<code>roots()</code>	Return the roots of the series polynomial.
<code>trim([tol])</code>	Remove trailing coefficients
<code>truncate(size)</code>	Truncate series to length <i>size</i> .

method

`polynomial.hermite_e.HermiteE.__call__(arg)`

Call self as a function.

method

classmethod `polynomial.hermite_e.HermiteE.basis(deg, domain=None, window=None, symbol='x')`

Series basis polynomial of degree *deg*.

Returns the series representing the basis polynomial of degree *deg*.

Parameters

deg

[int] Degree of the basis polynomial for the series. Must be ≥ 0 .

domain

[{None, array_like}, optional] If given, the array must be of the form `[beg, end]`, where *beg* and *end* are the endpoints of the domain. If None is given then the class domain is used. The default is None.

window

[{None, array_like}, optional] If given, the resulting array must be if the form `[beg, end]`, where *beg* and *end* are the endpoints of the window. If None is given then the class window is used. The default is None.

symbol

[str, optional] Symbol representing the independent variable. Default is 'x'.

Returns

new_series

[series] A series with the coefficient of the *deg* term set to one and all others zero.

method

classmethod `polynomial.hermite_e.HermiteE.cast` (*series, domain=None, window=None*)

Convert series to series of this class.

The *series* is expected to be an instance of some polynomial series of one of the types supported by the `numpy.polynomial` module, but could be some other class that supports the `convert` method.

Parameters**series**

[series] The series instance to be converted.

domain

[None, array_like], optional] If given, the array must be of the form `[beg, end]`, where `beg` and `end` are the endpoints of the domain. If `None` is given then the class domain is used. The default is `None`.

window

[None, array_like], optional] If given, the resulting array must be of the form `[beg, end]`, where `beg` and `end` are the endpoints of the window. If `None` is given then the class window is used. The default is `None`.

Returns**new_series**

[series] A series of the same kind as the calling class and equal to *series* when evaluated.

See also:**`convert`**

similar instance method

method

`polynomial.hermite_e.HermiteE.convert` (*domain=None, kind=None, window=None*)

Convert series to a different kind and/or domain and/or window.

Parameters**domain**

[array_like, optional] The domain of the converted series. If the value is `None`, the default domain of *kind* is used.

kind

[class, optional] The polynomial series type class to which the current instance should be converted. If *kind* is `None`, then the class of the current instance is used.

window

[array_like, optional] The window of the converted series. If the value is `None`, the default window of *kind* is used.

Returns**new_series**

[series] The returned class can be of different type than the current instance and/or have a different domain and/or different window.

Notes

Conversion between domains and class types can result in numerically ill defined series.

method

```
polynomial.hermite_e.HermiteE.copy()
```

Return a copy.

Returns

new_series

[series] Copy of self.

method

```
polynomial.hermite_e.HermiteE.cutdeg(deg)
```

Truncate series to the given degree.

Reduce the degree of the series to *deg* by discarding the high order terms. If *deg* is greater than the current degree a copy of the current series is returned. This can be useful in least squares where the coefficients of the high degree terms may be very small.

Parameters

deg

[non-negative int] The series is reduced to degree *deg* by discarding the high order terms. The value of *deg* must be a non-negative integer.

Returns

new_series

[series] New instance of series with reduced degree.

method

```
polynomial.hermite_e.HermiteE.degree()
```

The degree of the series.

Returns

degree

[int] Degree of the series, one less than the number of coefficients.

Examples

Create a polynomial object for $1 + 7x + 4x^2$:

```
>>> np.polynomial.set_default_printstyle("unicode")
>>> poly = np.polynomial.Polynomial([1, 7, 4])
>>> print(poly)
1.0 + 7.0·x + 4.0·x2
>>> poly.degree()
2
```

Note that this method does not check for non-zero coefficients. You must trim the polynomial to remove any trailing zeroes:

```

>>> poly = np.polynomial.Polynomial([1, 7, 0])
>>> print(poly)
1.0 + 7.0·x + 0.0·x2
>>> poly.degree()
2
>>> poly.trim().degree()
1

```

method

`polynomial.hermite_e.HermiteE.deriv(m=1)`

Differentiate.

Return a series instance of that is the derivative of the current series.

Parameters

m

[non-negative int] Find the derivative of order *m*.

Returns

new_series

[series] A new series representing the derivative. The domain is the same as the domain of the differentiated series.

method

classmethod `polynomial.hermite_e.HermiteE.fit(x, y, deg, domain=None, rcond=None, full=False, w=None, window=None, symbol='x')`

Least squares fit to data.

Return a series instance that is the least squares fit to the data *y* sampled at *x*. The domain of the returned instance can be specified and this will often result in a superior fit with less chance of ill conditioning.

Parameters

x

[array_like, shape (M,)] x-coordinates of the M sample points (*x*[*i*], *y*[*i*]).

y

[array_like, shape (M,)] y-coordinates of the M sample points (*x*[*i*], *y*[*i*]).

deg

[int or 1-D array_like] Degree(s) of the fitting polynomials. If *deg* is a single integer all terms up to and including the *deg*'th term are included in the fit. For NumPy versions $\geq 1.11.0$ a list of integers specifying the degrees of the terms to include may be used instead.

domain

[{None, [beg, end], []}, optional] Domain to use for the returned series. If *None*, then a minimal domain that covers the points *x* is chosen. If *[]* the class domain is used. The default value was the class domain in NumPy 1.4 and *None* in later versions. The *[]* option was added in numpy 1.5.0.

rcond

[float, optional] Relative condition number of the fit. Singular values smaller than this relative to the largest singular value will be ignored. The default value is `len(x)*eps`, where *eps* is the relative precision of the float type, about $2e-16$ in most cases.

full

[bool, optional] Switch determining nature of return value. When it is False (the default) just the coefficients are returned, when True diagnostic information from the singular value decomposition is also returned.

w

[array_like, shape (M,), optional] Weights. If not None, the weight $w[i]$ applies to the unsquared residual $y[i] - \hat{y}[i]$ at $x[i]$. Ideally the weights are chosen so that the errors of the products $w[i]*y[i]$ all have the same variance. When using inverse-variance weighting, use $w[i] = 1/\text{sigma}(y[i])$. The default value is None.

window

[[[beg, end]], optional] Window to use for the returned series. The default value is the default class domain

symbol

[str, optional] Symbol representing the independent variable. Default is 'x'.

Returns**new_series**

[series] A series that represents the least squares fit to the data and has the domain and window specified in the call. If the coefficients for the unscaled and unshifted basis polynomials are of interest, do `new_series.convert().coef`.

[resid, rank, sv, rcond]

[list] These values are only returned if `full == True`

- resid – sum of squared residuals of the least squares fit
- rank – the numerical rank of the scaled Vandermonde matrix
- sv – singular values of the scaled Vandermonde matrix
- rcond – value of *rcond*.

For more details, see [*linalg.lstsq*](#).

method

classmethod `polynomial.hermite_e.HermiteE.fromroots` (*roots*, *domain*=[], *window*=None, *symbol*='x')

Return series instance that has the specified roots.

Returns a series representing the product $(x - r[0]) * (x - r[1]) * \dots * (x - r[n-1])$, where *r* is a list of roots.

Parameters**roots**

[array_like] List of roots.

domain

[[[], None, array_like], optional] Domain for the resulting series. If None the domain is the interval from the smallest root to the largest. If [] the domain is the class domain. The default is [].

window

[None, array_like], optional] Window for the returned series. If None the class window is used. The default is None.

symbol

[str, optional] Symbol representing the independent variable. Default is 'x'.

Returns**new_series**

[series] Series with the specified roots.

method

`polynomial.hermite_e.HermiteE.has_samecoef(other)`

Check if coefficients match.

Parameters**other**

[class instance] The other class must have the `coef` attribute.

Returns**bool**

[boolean] True if the coefficients are the same, False otherwise.

method

`polynomial.hermite_e.HermiteE.has_samedomain(other)`

Check if domains match.

Parameters**other**

[class instance] The other class must have the `domain` attribute.

Returns**bool**

[boolean] True if the domains are the same, False otherwise.

method

`polynomial.hermite_e.HermiteE.has_sametype(other)`

Check if types match.

Parameters**other**

[object] Class instance.

Returns**bool**

[boolean] True if other is same class as self

method

`polynomial.hermite_e.HermiteE.has_samewindow(other)`

Check if windows match.

Parameters**other**

[class instance] The other class must have the `window` attribute.

Returns**bool**

[boolean] True if the windows are the same, False otherwise.

method

classmethod `polynomial.hermite_e.HermiteE.identity` (*domain=None, window=None, symbol='x'*)

Identity function.

If p is the returned series, then $p(x) == x$ for all values of x .

Parameters

domain

[*None*, array_like], optional] If given, the array must be of the form [*beg*, *end*], where *beg* and *end* are the endpoints of the domain. If *None* is given then the class domain is used. The default is *None*.

window

[*None*, array_like], optional] If given, the resulting array must be if the form [*beg*, *end*], where *beg* and *end* are the endpoints of the window. If *None* is given then the class window is used. The default is *None*.

symbol

[str, optional] Symbol representing the independent variable. Default is 'x'.

Returns

new_series

[series] Series of representing the identity.

method

`polynomial.hermite_e.HermiteE.integ` (*m=1, k=[], lbnd=None*)

Integrate.

Return a series instance that is the definite integral of the current series.

Parameters

m

[non-negative int] The number of integrations to perform.

k

[array_like] Integration constants. The first constant is applied to the first integration, the second to the second, and so on. The list of values must less than or equal to *m* in length and any missing values are set to zero.

lbnd

[Scalar] The lower bound of the definite integral.

Returns

new_series

[series] A new series representing the integral. The domain is the same as the domain of the integrated series.

method

`polynomial.hermite_e.HermiteE.linspace` (*n=100, domain=None*)

Return x , y values at equally spaced points in domain.

Returns the x , y values at n linearly spaced points across the domain. Here y is the value of the polynomial at the points x . By default the domain is the same as that of the series instance. This method is intended mostly as a plotting aid.

Parameters

n

[int, optional] Number of point pairs to return. The default value is 100.

domain[None, array_like], optional] If not None, the specified domain is used instead of that of the calling instance. It should be of the form `[beg, end]`. The default is None which case the class domain is used.**Returns****x, y**[ndarray] x is equal to `linspace(self.domain[0], self.domain[1], n)` and y is the series evaluated at element of x.

method

`polynomial.hermite_e.HermiteE.mapparms()`

Return the mapping parameters.

The returned values define a linear map $\text{off} + \text{scl} * x$ that is applied to the input arguments before the series is evaluated. The map depends on the `domain` and `window`; if the current `domain` is equal to the `window` the resulting map is the identity. If the coefficients of the series instance are to be used by themselves outside this class, then the linear function must be substituted for the `x` in the standard representation of the base polynomials.

Returns**off, scl**[float or complex] The mapping function is defined by $\text{off} + \text{scl} * x$.**Notes**

If the current domain is the interval $[l1, r1]$ and the window is $[l2, r2]$, then the linear mapping function L is defined by the equations:

$$\begin{aligned} L(l1) &= l2 \\ L(r1) &= r2 \end{aligned}$$

method

`polynomial.hermite_e.HermiteE.roots()`

Return the roots of the series polynomial.

Compute the roots for the series. Note that the accuracy of the roots decreases the further outside the domain they lie.

Returns**roots**

[ndarray] Array containing the roots of the series.

method

`polynomial.hermite_e.HermiteE.trim(tol=0)`

Remove trailing coefficients

Remove trailing coefficients until a coefficient is reached whose absolute value greater than `tol` or the beginning of the series is reached. If all the coefficients would be removed the series is set to `[0]`. A new series instance is returned with the new coefficients. The current instance remains unchanged.

Parameters

tol[non-negative number.] All trailing coefficients less than *tol* will be removed.**Returns****new_series**

[series] New instance of series with trimmed coefficients.

method

`polynomial.hermite_e.HermiteE.truncate(size)`Truncate series to length *size*.

Reduce the series to length *size* by discarding the high degree terms. The value of *size* must be a positive integer. This can be useful in least squares where the coefficients of the high degree terms may be very small.

Parameters**size**[positive int] The series is reduced to length *size* by discarding the high degree terms. The value of *size* must be a positive integer.**Returns****new_series**

[series] New instance of series with truncated coefficients.

Constants

<i>hermedomain</i>	<code>ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None)</code>
<i>hermezero</i>	<code>ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None)</code>
<i>hermeone</i>	<code>ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None)</code>
<i>hermex</i>	<code>ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None)</code>

`polynomial.hermite_e.hermedomain = array([-1., 1.])``ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None) –``ndarray(shape, dtype=np.float64, buffer=None, offset=0, strides=None, order=None)`

An array object represents a multidimensional, homogeneous array of fixed-size items. An associated data-type object describes the format of each element in the array (its byte-order, how many bytes it occupies in memory, whether it is an integer, a floating point number, or something else, etc.)

Arrays should be constructed using *array*, *zeros* or *empty* (refer to the See Also section below). The parameters given here refer to a low-level method (*ndarray(...)*) for instantiating an array.

For more information, refer to the *numpy* module and examine the methods and attributes of an array.

Parameters**(for the `__new__` method; see Notes below)****shape**

[tuple of ints] Shape of created array.

dtype

[data-type, optional] Any object that can be interpreted as a numpy data type. Default is `numpy.float64`.

buffer

[object exposing buffer interface, optional] Used to fill the array with data.

offset

[int, optional] Offset of array data in buffer.

strides

[tuple of ints, optional] Strides of data in memory.

order

[{'C', 'F'}, optional] Row-major (C-style) or column-major (Fortran-style) order.

Attributes**T**

[ndarray] Transpose of the array.

data

[buffer] The array's elements, in memory.

dtype

[dtype object] Describes the format of the elements in the array.

flags

[dict] Dictionary containing information related to memory use, e.g., 'C_CONTIGUOUS', 'OWNDATA', 'WRITEABLE', etc.

flat

[numpy.flatiter object] Flattened version of the array as an iterator. The iterator allows assignments, e.g., `x.flat = 3` (See `ndarray.flat` for assignment examples; TODO).

imag

[ndarray] Imaginary part of the array.

real

[ndarray] Real part of the array.

size

[int] Number of elements in the array.

itemsize

[int] The memory use of each array element in bytes.

nbytes

[int] The total number of bytes required to store the array data, i.e., `itemsize * size`.

ndim

[int] The array's number of dimensions.

shape

[tuple of ints] Shape of the array.

strides

[tuple of ints] The step-size required to move from one element to the next in memory. For example, a contiguous (3, 4) array of type `int16` in C-order has strides (8, 2). This implies that to move from element to element in memory requires jumps of 2 bytes. To move from row-to-row, one needs to jump 8 bytes at a time (2 * 4).

ctypes

[ctypes object] Class containing properties of the array needed for interaction with ctypes.

base

[ndarray] If the array is a view into another array, that array is its *base* (unless that array is also a view). The *base* array is where the array data is actually stored.

See also:**array**

Construct an array.

zeros

Create an array, each element of which is zero.

empty

Create an array, but leave its allocated memory unchanged (i.e., it contains “garbage”).

dtype

Create a data-type.

numpy.typing.NDArray

An ndarray alias *generic* w.r.t. its *dtype.type*.

Notes

There are two modes of creating an array using `__new__`:

1. If *buffer* is None, then only *shape*, *dtype*, and *order* are used.
2. If *buffer* is an object exposing the buffer interface, then all keywords are interpreted.

No `__init__` method is needed because the array is fully initialized after the `__new__` method.

Examples

These examples illustrate the low-level *ndarray* constructor. Refer to the *See Also* section above for easier ways of constructing an ndarray.

First mode, *buffer* is None:

```
>>> import numpy as np
>>> np.ndarray(shape=(2,2), dtype=np.float64, order='F')
array([[0.0e+000, 0.0e+000], # random
       [      nan, 2.5e-323]])
```

Second mode:

```
>>> np.ndarray((2,), buffer=np.array([1,2,3]),
...           offset=np.int_().itemsize,
...           dtype=np.int_) # offset = 1*itemsize, i.e. skip first element
array([2, 3])
```

```
polynomial.hermite_e.hermzero = array([0])
```

```
ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None) –
```

```
ndarray(shape, dtype=np.float64, buffer=None, offset=0, strides=None, order=None)
```

An array object represents a multidimensional, homogeneous array of fixed-size items. An associated data-type object describes the format of each element in the array (its byte-order, how many bytes it occupies in memory, whether it is an integer, a floating point number, or something else, etc.)

Arrays should be constructed using `array`, `zeros` or `empty` (refer to the See Also section below). The parameters given here refer to a low-level method (`ndarray(...)`) for instantiating an array.

For more information, refer to the `numpy` module and examine the methods and attributes of an array.

Parameters

(for the `__new__` method; see Notes below)

shape

[tuple of ints] Shape of created array.

dtype

[data-type, optional] Any object that can be interpreted as a numpy data type. Default is `numpy.float64`.

buffer

[object exposing buffer interface, optional] Used to fill the array with data.

offset

[int, optional] Offset of array data in buffer.

strides

[tuple of ints, optional] Strides of data in memory.

order

[['C', 'F'], optional] Row-major (C-style) or column-major (Fortran-style) order.

Attributes

T

[ndarray] Transpose of the array.

data

[buffer] The array's elements, in memory.

dtype

[dtype object] Describes the format of the elements in the array.

flags

[dict] Dictionary containing information related to memory use, e.g., 'C_CONTIGUOUS', 'OWNDATA', 'WRITEABLE', etc.

flat

[numpy.flatiter object] Flattened version of the array as an iterator. The iterator allows assignments, e.g., `x.flat = 3` (See `ndarray.flat` for assignment examples; TODO).

imag

[ndarray] Imaginary part of the array.

real

[ndarray] Real part of the array.

size

[int] Number of elements in the array.

itemsize

[int] The memory use of each array element in bytes.

nbytes

[int] The total number of bytes required to store the array data, i.e., `itemsize * size`.

ndim

[int] The array's number of dimensions.

shape

[tuple of ints] Shape of the array.

strides

[tuple of ints] The step-size required to move from one element to the next in memory. For example, a contiguous (3, 4) array of type `int16` in C-order has strides (8, 2). This implies that to move from element to element in memory requires jumps of 2 bytes. To move from row-to-row, one needs to jump 8 bytes at a time ($2 * 4$).

ctypes

[ctypes object] Class containing properties of the array needed for interaction with ctypes.

base

[ndarray] If the array is a view into another array, that array is its *base* (unless that array is also a view). The *base* array is where the array data is actually stored.

See also:**`array`**

Construct an array.

`zeros`

Create an array, each element of which is zero.

`empty`

Create an array, but leave its allocated memory unchanged (i.e., it contains “garbage”).

`dtype`

Create a data-type.

`numpy.typing.NDArray`

An ndarray alias *generic* w.r.t. its `dtype.type`.

Notes

There are two modes of creating an array using `__new__`:

1. If *buffer* is None, then only *shape*, *dtype*, and *order* are used.
2. If *buffer* is an object exposing the buffer interface, then all keywords are interpreted.

No `__init__` method is needed because the array is fully initialized after the `__new__` method.

Examples

These examples illustrate the low-level `ndarray` constructor. Refer to the *See Also* section above for easier ways of constructing an ndarray.

First mode, *buffer* is None:

```
>>> import numpy as np
>>> np.ndarray(shape=(2,2), dtype=np.float64, order='F')
array([[0.0e+000, 0.0e+000], # random
       [      nan, 2.5e-323]])
```

Second mode:

```
>>> np.ndarray((2,), buffer=np.array([1,2,3]),
...           offset=np.int_().itemsize,
...           dtype=np.int_) # offset = 1*itemsize, i.e. skip first element
array([2, 3])
```

```
polynomial.hermite_e.hermione = array([1])
```

```
ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None) -
```

```
ndarray(shape, dtype=np.float64, buffer=None, offset=0, strides=None, order=None)
```

An array object represents a multidimensional, homogeneous array of fixed-size items. An associated data-type object describes the format of each element in the array (its byte-order, how many bytes it occupies in memory, whether it is an integer, a floating point number, or something else, etc.)

Arrays should be constructed using *array*, *zeros* or *empty* (refer to the See Also section below). The parameters given here refer to a low-level method (*ndarray(...)*) for instantiating an array.

For more information, refer to the *numpy* module and examine the methods and attributes of an array.

Parameters

(for the `__new__` method; see Notes below)

shape

[tuple of ints] Shape of created array.

dtype

[data-type, optional] Any object that can be interpreted as a numpy data type. Default is *numpy.float64*.

buffer

[object exposing buffer interface, optional] Used to fill the array with data.

offset

[int, optional] Offset of array data in buffer.

strides

[tuple of ints, optional] Strides of data in memory.

order

[['C', 'F'], optional] Row-major (C-style) or column-major (Fortran-style) order.

Attributes

T

[ndarray] Transpose of the array.

data

[buffer] The array's elements, in memory.

dtype

[dtype object] Describes the format of the elements in the array.

flags

[dict] Dictionary containing information related to memory use, e.g., 'C_CONTIGUOUS', 'OWNDATA', 'WRITEABLE', etc.

flat

[numpy.flatiter object] Flattened version of the array as an iterator. The iterator allows assignments, e.g., `x.flat = 3` (See *ndarray.flat* for assignment examples; TODO).

imag

[ndarray] Imaginary part of the array.

real

[ndarray] Real part of the array.

size

[int] Number of elements in the array.

itemsize

[int] The memory use of each array element in bytes.

nbytes

[int] The total number of bytes required to store the array data, i.e., `itemsize * size`.

ndim

[int] The array's number of dimensions.

shape

[tuple of ints] Shape of the array.

strides

[tuple of ints] The step-size required to move from one element to the next in memory. For example, a contiguous (3, 4) array of type `int16` in C-order has strides (8, 2). This implies that to move from element to element in memory requires jumps of 2 bytes. To move from row-to-row, one needs to jump 8 bytes at a time (2 * 4).

ctypes

[ctypes object] Class containing properties of the array needed for interaction with ctypes.

base

[ndarray] If the array is a view into another array, that array is its *base* (unless that array is also a view). The *base* array is where the array data is actually stored.

See also:**`array`**

Construct an array.

`zeros`

Create an array, each element of which is zero.

`empty`

Create an array, but leave its allocated memory unchanged (i.e., it contains “garbage”).

`dtype`

Create a data-type.

`numpy.typing.NDArray`

An ndarray alias *generic* w.r.t. its `dtype.type`.

Notes

There are two modes of creating an array using `__new__`:

1. If *buffer* is None, then only *shape*, *dtype*, and *order* are used.
2. If *buffer* is an object exposing the buffer interface, then all keywords are interpreted.

No `__init__` method is needed because the array is fully initialized after the `__new__` method.

Examples

These examples illustrate the low-level `ndarray` constructor. Refer to the *See Also* section above for easier ways of constructing an ndarray.

First mode, `buffer` is `None`:

```
>>> import numpy as np
>>> np.ndarray(shape=(2,2), dtype=np.float64, order='F')
array([[0.0e+000, 0.0e+000], # random
       [      nan, 2.5e-323]])
```

Second mode:

```
>>> np.ndarray((2,), buffer=np.array([1,2,3]),
...           offset=np.int_().itemsize,
...           dtype=np.int_) # offset = 1*itemsize, i.e. skip first element
array([2, 3])
```

```
polynomial.hermite_e.hermex = array([0, 1])
```

```
ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None) -
```

```
ndarray(shape, dtype=np.float64, buffer=None, offset=0, strides=None, order=None)
```

An array object represents a multidimensional, homogeneous array of fixed-size items. An associated data-type object describes the format of each element in the array (its byte-order, how many bytes it occupies in memory, whether it is an integer, a floating point number, or something else, etc.)

Arrays should be constructed using `array`, `zeros` or `empty` (refer to the *See Also* section below). The parameters given here refer to a low-level method (`ndarray(...)`) for instantiating an array.

For more information, refer to the `numpy` module and examine the methods and attributes of an array.

Parameters

(for the `__new__` method; see Notes below)

shape

[tuple of ints] Shape of created array.

dtype

[data-type, optional] Any object that can be interpreted as a numpy data type. Default is `numpy.float64`.

buffer

[object exposing buffer interface, optional] Used to fill the array with data.

offset

[int, optional] Offset of array data in buffer.

strides

[tuple of ints, optional] Strides of data in memory.

order

[{'C', 'F'}, optional] Row-major (C-style) or column-major (Fortran-style) order.

Attributes

T

[ndarray] Transpose of the array.

data

[buffer] The array's elements, in memory.

dtype

[dtype object] Describes the format of the elements in the array.

flags

[dict] Dictionary containing information related to memory use, e.g., 'C_CONTIGUOUS', 'OWNDATA', 'WRITEABLE', etc.

flat

[numpy.flatiter object] Flattened version of the array as an iterator. The iterator allows assignments, e.g., `x.flat = 3` (See [ndarray.flat](#) for assignment examples; TODO).

imag

[ndarray] Imaginary part of the array.

real

[ndarray] Real part of the array.

size

[int] Number of elements in the array.

itemsize

[int] The memory use of each array element in bytes.

nbytes

[int] The total number of bytes required to store the array data, i.e., `itemsize * size`.

ndim

[int] The array's number of dimensions.

shape

[tuple of ints] Shape of the array.

strides

[tuple of ints] The step-size required to move from one element to the next in memory. For example, a contiguous `(3, 4)` array of type `int16` in C-order has strides `(8, 2)`. This implies that to move from element to element in memory requires jumps of 2 bytes. To move from row-to-row, one needs to jump 8 bytes at a time (`2 * 4`).

ctypes

[ctypes object] Class containing properties of the array needed for interaction with ctypes.

base

[ndarray] If the array is a view into another array, that array is its *base* (unless that array is also a view). The *base* array is where the array data is actually stored.

See also:**`array`**

Construct an array.

`zeros`

Create an array, each element of which is zero.

`empty`

Create an array, but leave its allocated memory unchanged (i.e., it contains "garbage").

`dtype`

Create a data-type.

`numpy.typing.NDArray`

An ndarray alias *generic* w.r.t. its `dtype.type`.

Notes

There are two modes of creating an array using `__new__`:

1. If *buffer* is None, then only *shape*, *dtype*, and *order* are used.
2. If *buffer* is an object exposing the buffer interface, then all keywords are interpreted.

No `__init__` method is needed because the array is fully initialized after the `__new__` method.

Examples

These examples illustrate the low-level *ndarray* constructor. Refer to the *See Also* section above for easier ways of constructing an ndarray.

First mode, *buffer* is None:

```
>>> import numpy as np
>>> np.ndarray(shape=(2,2), dtype=np.float64, order='F')
array([[0.0e+000, 0.0e+000], # random
       [      nan, 2.5e-323]])
```

Second mode:

```
>>> np.ndarray((2,), buffer=np.array([1,2,3]),
...           offset=np.int_().itemsize,
...           dtype=np.int_) # offset = 1*itemsize, i.e. skip first element
array([2, 3])
```

Arithmetic

<i>hermeadd</i> (c1, c2)	Add one Hermite series to another.
<i>hermesub</i> (c1, c2)	Subtract one Hermite series from another.
<i>hermemulx</i> (c)	Multiply a Hermite series by x.
<i>hermemul</i> (c1, c2)	Multiply one Hermite series by another.
<i>hermediv</i> (c1, c2)	Divide one Hermite series by another.
<i>hermepow</i> (c, pow[, maxpower])	Raise a Hermite series to a power.
<i>hermeval</i> (x, c[, tensor])	Evaluate a HermiteE series at points x.
<i>hermeval2d</i> (x, y, c)	Evaluate a 2-D HermiteE series at points (x, y).
<i>hermeval3d</i> (x, y, z, c)	Evaluate a 3-D Hermite_e series at points (x, y, z).
<i>hermevalnd</i> (pts, c)	Evaluate an N-D Hermite_e series at points.
<i>hermegrid2d</i> (x, y, c)	Evaluate a 2-D HermiteE series on the Cartesian product of x and y.
<i>hermegrid3d</i> (x, y, z, c)	Evaluate a 3-D HermiteE series on the Cartesian product of x, y, and z.

`polynomial.hermite_e.hermeadd(c1, c2)`

Add one Hermite series to another.

Returns the sum of two Hermite series *c1* + *c2*. The arguments are sequences of coefficients ordered from lowest order term to highest, i.e., [1,2,3] represents the series $P_0 + 2P_1 + 3P_2$.

Parameters

c1, c2

[array_like] 1-D arrays of Hermite series coefficients ordered from low to high.

Returns**out**

[ndarray] Array representing the Hermite series of their sum.

See also:*hermesub, hermемulx, hermемul, hermediv, hermepow***Notes**

Unlike multiplication, division, etc., the sum of two Hermite series is a Hermite series (without having to “reproject” the result onto the basis set) so addition, just like that of “standard” polynomials, is simply “component-wise.”

Examples

```
>>> from numpy.polynomial.hermite_e import hermeadd
>>> hermeadd([1, 2, 3], [1, 2, 3, 4])
array([2., 4., 6., 4.] )
```

`polynomial.hermite_e.hermesub(c1, c2)`

Subtract one Hermite series from another.

Returns the difference of two Hermite series $c1 - c2$. The sequences of coefficients are from lowest order term to highest, i.e., [1,2,3] represents the series $P_0 + 2*P_1 + 3*P_2$.

Parameters**c1, c2**

[array_like] 1-D arrays of Hermite series coefficients ordered from low to high.

Returns**out**

[ndarray] Of Hermite series coefficients representing their difference.

See also:*hermeadd, hermемulx, hermемul, hermediv, hermepow***Notes**

Unlike multiplication, division, etc., the difference of two Hermite series is a Hermite series (without having to “reproject” the result onto the basis set) so subtraction, just like that of “standard” polynomials, is simply “component-wise.”

Examples

```
>>> from numpy.polynomial.hermite_e import hermesub
>>> hermesub([1, 2, 3, 4], [1, 2, 3])
array([0., 0., 0., 4.]
```

`polynomial.hermite_e.hermemulx(c)`

Multiply a Hermite series by x.

Multiply the Hermite series *c* by x, where x is the independent variable.

Parameters

c
[array_like] 1-D array of Hermite series coefficients ordered from low to high.

Returns

out
[ndarray] Array representing the result of the multiplication.

See also:

[*hermeadd*](#), [*hermesub*](#), [*hermemul*](#), [*hermediv*](#), [*hermepow*](#)

Notes

The multiplication uses the recursion relationship for Hermite polynomials in the form

$$xP_i(x) = (P_{i+1}(x) + iP_{i-1}(x))$$

Examples

```
>>> from numpy.polynomial.hermite_e import hermemulx
>>> hermemulx([1, 2, 3])
array([2., 7., 2., 3.]
```

`polynomial.hermite_e.hermemul(c1, c2)`

Multiply one Hermite series by another.

Returns the product of two Hermite series *c1* * *c2*. The arguments are sequences of coefficients, from lowest order “term” to highest, e.g., [1,2,3] represents the series $P_0 + 2P_1 + 3P_2$.

Parameters

c1, c2
[array_like] 1-D arrays of Hermite series coefficients ordered from low to high.

Returns

out
[ndarray] Of Hermite series coefficients representing their product.

See also:

[*hermeadd*](#), [*hermesub*](#), [*hermemulx*](#), [*hermediv*](#), [*hermepow*](#)

Notes

In general, the (polynomial) product of two C-series results in terms that are not in the Hermite polynomial basis set. Thus, to express the product as a Hermite series, it is necessary to “reproject” the product onto said basis set, which may produce “unintuitive” (but correct) results; see Examples section below.

Examples

```
>>> from numpy.polynomial.hermite_e import hermemul
>>> hermemul([1, 2, 3], [0, 1, 2])
array([14., 15., 28., 7., 6.] )
```

`polynomial.hermite_e.hermdiv(c1, c2)`

Divide one Hermite series by another.

Returns the quotient-with-remainder of two Hermite series $c1 / c2$. The arguments are sequences of coefficients from lowest order “term” to highest, e.g., [1,2,3] represents the series $P_0 + 2P_1 + 3P_2$.

Parameters

c1, c2

[array_like] 1-D arrays of Hermite series coefficients ordered from low to high.

Returns

[quo, rem]

[ndarrays] Of Hermite series coefficients representing the quotient and remainder.

See also:

hermeadd, hermesub, hermemulx, hermemul, hermepow

Notes

In general, the (polynomial) division of one Hermite series by another results in quotient and remainder terms that are not in the Hermite polynomial basis set. Thus, to express these results as a Hermite series, it is necessary to “reproject” the results onto the Hermite basis set, which may produce “unintuitive” (but correct) results; see Examples section below.

Examples

```
>>> from numpy.polynomial.hermite_e import hermediv
>>> hermediv([ 14., 15., 28., 7., 6.], [0, 1, 2])
(array([1., 2., 3.]), array([0.]))
>>> hermediv([ 15., 17., 28., 7., 6.], [0, 1, 2])
(array([1., 2., 3.]), array([1., 2.]))
```

`polynomial.hermite_e.hermepow(c, pow, maxpower=16)`

Raise a Hermite series to a power.

Returns the Hermite series c raised to the power pow . The argument c is a sequence of coefficients ordered from low to high. i.e., [1,2,3] is the series $P_0 + 2P_1 + 3P_2$.

Parameters

c
[array_like] 1-D array of Hermite series coefficients ordered from low to high.

pow
[integer] Power to which the series will be raised

maxpower
[integer, optional] Maximum power allowed. This is mainly to limit growth of the series to unmanageable size. Default is 16

Returns

coef
[ndarray] Hermite series of power.

See also:

[*hermeadd*](#), [*hermesub*](#), [*hermemulx*](#), [*hermemul*](#), [*hermediv*](#)

Examples

```
>>> from numpy.polynomial.hermite_e import hermepow
>>> hermepow([1, 2, 3], 2)
array([23., 28., 46., 12., 9.]
```

`polynomial.hermite_e.hermeval` (*x*, *c*, *tensor=True*)

Evaluate a HermiteE series at points *x*.

If *c* is of length $n + 1$, this function returns the value:

$$p(x) = c_0 * He_0(x) + c_1 * He_1(x) + ... + c_n * He_n(x)$$

The parameter *x* is converted to an array only if it is a tuple or a list, otherwise it is treated as a scalar. In either case, either *x* or its elements must support multiplication and addition both with themselves and with the elements of *c*.

If *c* is a 1-D array, then $p(x)$ will have the same shape as *x*. If *c* is multidimensional, then the shape of the result depends on the value of *tensor*. If *tensor* is true the shape will be $c.shape[1:] + x.shape$. If *tensor* is false the shape will be $c.shape[1:]$. Note that scalars have shape $()$.

Trailing zeros in the coefficients will be used in the evaluation, so they should be avoided if efficiency is a concern.

Parameters

x
[array_like, compatible object] If *x* is a list or tuple, it is converted to an ndarray, otherwise it is left unchanged and treated as a scalar. In either case, *x* or its elements must support addition and multiplication with themselves and with the elements of *c*.

c
[array_like] Array of coefficients ordered so that the coefficients for terms of degree *n* are contained in $c[n]$. If *c* is multidimensional the remaining indices enumerate multiple polynomials. In the two dimensional case the coefficients may be thought of as stored in the columns of *c*.

tensor
[boolean, optional] If True, the shape of the coefficient array is extended with ones on the right, one for each dimension of *x*. Scalars have dimension 0 for this action. The result is that every column of coefficients in *c* is evaluated for every element of *x*. If False, *x* is broadcast

over the columns of c for the evaluation. This keyword is useful when c is multidimensional. The default value is True.

Returns

values

[ndarray, algebra_like] The shape of the return value is described above.

See also:

[*hermeval1d*](#), [*hermegrid2d*](#), [*hermeval3d*](#), [*hermegrid3d*](#)

Notes

The evaluation uses Clenshaw recursion, aka synthetic division.

Examples

```
>>> from numpy.polynomial.hermite_e import hermeval
>>> coef = [1,2,3]
>>> hermeval(1, coef)
3.0
>>> hermeval([[1,2],[3,4]], coef)
array([[ 3., 14.],
       [31., 54.]])
```

`polynomial.hermite_e.hermeval2d`(x, y, c)

Evaluate a 2-D HermiteE series at points (x, y).

This function returns the values:

$$p(x, y) = \sum_{i,j} c_{i,j} * He_i(x) * He_j(y)$$

The parameters x and y are converted to arrays only if they are tuples or a lists, otherwise they are treated as a scalars and they must have the same shape after conversion. In either case, either x and y or their elements must support multiplication and addition both with themselves and with the elements of c .

If c is a 1-D array a one is implicitly appended to its shape to make it 2-D. The shape of the result will be $c.shape[2:] + x.shape$.

Parameters

x, y

[array_like, compatible objects] The two dimensional series is evaluated at the points (x, y), where x and y must have the same shape. If x or y is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and if it isn't an ndarray it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficient of the term of multi-degree i, j is contained in $c[i, j]$. If c has dimension greater than two the remaining indices enumerate multiple sets of coefficients.

Returns

values

[ndarray, compatible object] The values of the two dimensional polynomial at points formed with pairs of corresponding values from x and y .

See also:

[*hermeval*](#), [*hermegrid2d*](#), [*hermeval3d*](#), [*hermegrid3d*](#)

`polynomial.hermite_e.hermeval3d(x, y, z, c)`

Evaluate a 3-D Hermite_e series at points (x, y, z).

This function returns the values:

$$p(x, y, z) = \sum_{i,j,k} c_{i,j,k} * He_i(x) * He_j(y) * He_k(z)$$

The parameters x , y , and z are converted to arrays only if they are tuples or a lists, otherwise they are treated as a scalars and they must have the same shape after conversion. In either case, either x , y , and z or their elements must support multiplication and addition both with themselves and with the elements of c .

If c has fewer than 3 dimensions, ones are implicitly appended to its shape to make it 3-D. The shape of the result will be $c.shape[3:] + x.shape$.

Parameters

x, y, z

[array_like, compatible object] The three dimensional series is evaluated at the points (x , y , z), where x , y , and z must have the same shape. If any of x , y , or z is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and if it isn't an ndarray it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficient of the term of multi-degree i,j,k is contained in $c[i, j, k]$. If c has dimension greater than 3 the remaining indices enumerate multiple sets of coefficients.

Returns

values

[ndarray, compatible object] The values of the multidimensional polynomial on points formed with triples of corresponding values from x , y , and z .

See also:

[*hermeval*](#), [*hermeval2d*](#), [*hermegrid2d*](#), [*hermegrid3d*](#)

`polynomial.hermite_e.hermevalnd(pts, c)`

Evaluate an N-D Hermite_e series at points.

This function returns the values:

$$p(pts, c) = \sum_{i_1, i_2, \dots, i_n} c_{i_1, i_2, \dots, i_n} * He_{i_1}(x_1) * He_{i_2}(x_2) \dots He_{i_n}(x_n)$$

where $x_1, x_2, \dots, x_n = pts$. Note that pts may also be an (n, m) array.

The parameters in pts are converted to arrays only if they are tuples or lists, otherwise they are treated as scalars and they must have the same shape after conversion. In either case, either the elements of pts or their elements must support multiplication and addition both with themselves and with the elements of c .

If c has fewer than N dimensions, ones are implicitly appended to its shape to make it N-D. The shape of the result will be $c.shape[N:] + pts[0].shape$.

Parameters

pts

[tuple or list of array_like, compatible objects] The N-dimensional series is evaluated at the points $(x_1, x_2, \dots, x_n)$ provided in the *pts* iterable, where all elements must have the same shape. If any element is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and if it isn't an ndarray it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficient of the term of multi-degree $i,j,k,\dots$ is contained in $c[i, j, k, \dots]$. If *c* has dimension greater than N, the remaining indices enumerate multiple sets of coefficients.

Returns**values**

[ndarray, compatible object] The values of the multidimensional polynomial on points formed with N-tuples of corresponding values from *pts*.

See also:[*hermeval*](#), [*hermeval2d*](#), [*hermeval3d*](#)`polynomial.hermite_e.hermegrid2d(x, y, c)`

Evaluate a 2-D HermiteE series on the Cartesian product of *x* and *y*.

This function returns the values:

$$p(a, b) = \sum_{i,j} c_{i,j} * H_i(a) * H_j(b)$$

where the points (a, b) consist of all pairs formed by taking *a* from *x* and *b* from *y*. The resulting points form a grid with *x* in the first dimension and *y* in the second.

The parameters *x* and *y* are converted to arrays only if they are tuples or a lists, otherwise they are treated as a scalars. In either case, either *x* and *y* or their elements must support multiplication and addition both with themselves and with the elements of *c*.

If *c* has fewer than two dimensions, ones are implicitly appended to its shape to make it 2-D. The shape of the result will be $c.shape[2:] + x.shape$.

Parameters**x, y**

[array_like, compatible objects] The two dimensional series is evaluated at the points in the Cartesian product of *x* and *y*. If *x* or *y* is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and, if it isn't an ndarray, it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficients for terms of degree i,j are contained in $c[i, j]$. If *c* has dimension greater than two the remaining indices enumerate multiple sets of coefficients.

Returns**values**

[ndarray, compatible object] The values of the two dimensional polynomial at points in the Cartesian product of *x* and *y*.

See also:[*hermeval*](#), [*hermeval2d*](#), [*hermeval3d*](#), [*hermegrid3d*](#)

`polynomial.hermite_e.hermegrid3d(x, y, z, c)`

Evaluate a 3-D HermiteE series on the Cartesian product of x , y , and z .

This function returns the values:

$$p(a, b, c) = \sum_{i,j,k} c_{i,j,k} * He_i(a) * He_j(b) * He_k(c)$$

where the points (a, b, c) consist of all triples formed by taking a from x , b from y , and c from z . The resulting points form a grid with x in the first dimension, y in the second, and z in the third.

The parameters x , y , and z are converted to arrays only if they are tuples or a lists, otherwise they are treated as a scalars. In either case, either x , y , and z or their elements must support multiplication and addition both with themselves and with the elements of c .

If c has fewer than three dimensions, ones are implicitly appended to its shape to make it 3-D. The shape of the result will be $c.shape[3:] + x.shape + y.shape + z.shape$.

Parameters

x, y, z

[array_like, compatible objects] The three dimensional series is evaluated at the points in the Cartesian product of x , y , and z . If x , y , or z is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and, if it isn't an ndarray, it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficients for terms of degree i, j are contained in $c[i, j]$. If c has dimension greater than two the remaining indices enumerate multiple sets of coefficients.

Returns

values

[ndarray, compatible object] The values of the two dimensional polynomial at points in the Cartesian product of x and y .

Calculus

<code>hermeder(c[, m, scl, axis])</code>	Differentiate a Hermite_e series.
<code>hermeint(c[, m, k, lbnd, scl, axis])</code>	Integrate a Hermite_e series.

`polynomial.hermite_e.hermeder(c, m=1, scl=1, axis=0)`

Differentiate a Hermite_e series.

Returns the series coefficients c differentiated m times along $axis$. At each iteration the result is multiplied by scl (the scaling factor is for use in a linear change of variable). The argument c is an array of coefficients from low to high degree along each axis, e.g., $[1,2,3]$ represents the series $1*He_0 + 2*He_1 + 3*He_2$ while $[[1,2],[1,2]]$ represents $1*He_0(x)*He_0(y) + 1*He_1(x)*He_0(y) + 2*He_0(x)*He_1(y) + 2*He_1(x)*He_1(y)$ if $axis=0$ is x and $axis=1$ is y .

Parameters

c
[array_like] Array of Hermite_e series coefficients. If *c* is multidimensional the different axis correspond to different variables with the degree in each axis given by the corresponding index.

m
[int, optional] Number of derivatives taken, must be non-negative. (Default: 1)

scl
[scalar, optional] Each differentiation is multiplied by *scl*. The end result is multiplication by *scl***m*. This is for use in a linear change of variable. (Default: 1)

axis
[int, optional] Axis over which the derivative is taken. (Default: 0).

Returns

der
[ndarray] Hermite series of the derivative.

See also:

[*hermeint*](#)

Notes

In general, the result of differentiating a Hermite series does not resemble the same operation on a power series. Thus the result of this function may be “unintuitive,” albeit correct; see Examples section below.

Examples

```
>>> from numpy.polynomial.hermite_e import hermeder
>>> hermeder([ 1., 1., 1., 1.])
array([1., 2., 3.])
>>> hermeder([-0.25, 1., 1./2., 1./3., 1./4.], m=2)
array([1., 2., 3.])
```

`polynomial.hermite_e.hermeint` (*c*, *m*=1, *k*=[], *lbnd*=0, *scl*=1, *axis*=0)

Integrate a Hermite_e series.

Returns the Hermite_e series coefficients *c* integrated *m* times from *lbnd* along *axis*. At each iteration the resulting series is **multiplied** by *scl* and an integration constant, *k*, is added. The scaling factor is for use in a linear change of variable. (“Buyer beware”: note that, depending on what one is doing, one may want *scl* to be the reciprocal of what one might expect; for more information, see the Notes section below.) The argument *c* is an array of coefficients from low to high degree along each axis, e.g., [1,2,3] represents the series $H_0 + 2H_1 + 3H_2$ while [[1,2],[1,2]] represents $1H_0(x)H_0(y) + 1H_1(x)H_0(y) + 2H_0(x)H_1(y) + 2H_1(x)H_1(y)$ if *axis*=0 is *x* and *axis*=1 is *y*.

Parameters

c
[array_like] Array of Hermite_e series coefficients. If *c* is multidimensional the different axis correspond to different variables with the degree in each axis given by the corresponding index.

m
[int, optional] Order of integration, must be positive. (Default: 1)

k

[[], list, scalar], optional] Integration constant(s). The value of the first integral at `lbnd` is the first value in the list, the value of the second integral at `lbnd` is the second value, etc. If `k == []` (the default), all constants are set to zero. If `m == 1`, a single scalar can be given instead of a list.

lbnd

[scalar, optional] The lower bound of the integral. (Default: 0)

scl

[scalar, optional] Following each integration the result is *multiplied* by `scl` before the integration constant is added. (Default: 1)

axis

[int, optional] Axis over which the integral is taken. (Default: 0).

Returns**S**

[ndarray] Hermite_e series coefficients of the integral.

Raises**ValueError**

If `m < 0`, `len(k) > m`, `np.ndim(lbnd) != 0`, or `np.ndim(scl) != 0`.

See also:

[*hermeder*](#)

Notes

Note that the result of each integration is *multiplied* by `scl`. Why is this important to note? Say one is making a linear change of variable $u = ax + b$ in an integral relative to x . Then $dx = du/a$, so one will need to set `scl` equal to $1/a$ - perhaps not what one would have first thought.

Also note that, in general, the result of integrating a C-series needs to be “reprojected” onto the C-series basis set. Thus, typically, the result of this function is “unintuitive,” albeit correct; see Examples section below.

Examples

```
>>> from numpy.polynomial.hermite_e import hermeint
>>> hermeint([1, 2, 3]) # integrate once, value 0 at 0.
array([1., 1., 1., 1.])
>>> hermeint([1, 2, 3], m=2) # integrate twice, value & deriv 0 at 0
array([-0.25      ,  1.          ,  0.5          ,  0.33333333,  0.25      ]) # may
↪ vary
>>> hermeint([1, 2, 3], k=1) # integrate once, value 1 at 0.
array([2., 1., 1., 1.])
>>> hermeint([1, 2, 3], lbnd=-1) # integrate once, value 0 at -1
array([-1.,  1.,  1.,  1.])
>>> hermeint([1, 2, 3], m=2, k=[1, 2], lbnd=-1)
array([ 1.83333333,  0.          ,  0.5          ,  0.33333333,  0.25      ]) # may
↪ vary
```

Misc Functions

<code>hermefromroots</code> (roots)	Generate a HermiteE series with given roots.
<code>hermeroots</code> (c)	Compute the roots of a HermiteE series.
<code>hermevander</code> (x, deg)	Pseudo-Vandermonde matrix of given degree.
<code>hermevander2d</code> (x, y, deg)	Pseudo-Vandermonde matrix of given degrees.
<code>hermevander3d</code> (x, y, z, deg)	Pseudo-Vandermonde matrix of given degrees.
<code>hermegauss</code> (deg)	Gauss-Hermite quadrature.
<code>hermeweight</code> (x)	Weight function of the Hermite_e polynomials.
<code>hermecompanion</code> (c)	Return the scaled companion matrix of c.
<code>hermefit</code> (x, y, deg[, rcond, full, w])	Least squares fit of Hermite series to data.
<code>hermetrim</code> (c[, tol])	Remove "small" "trailing" coefficients from a polynomial.
<code>hermeline</code> (off, scl)	Hermite series whose graph is a straight line.
<code>herme2poly</code> (c)	Convert a Hermite series to a polynomial.
<code>poly2herme</code> (pol)	Convert a polynomial to a Hermite series.

`polynomial.hermite_e.hermefromroots` (roots)

Generate a HermiteE series with given roots.

The function returns the coefficients of the polynomial

$$p(x) = (x - r_0) * (x - r_1) * \dots * (x - r_n),$$

in HermiteE form, where the r_n are the roots specified in `roots`. If a zero has multiplicity n , then it must appear in `roots` n times. For instance, if 2 is a root of multiplicity three and 3 is a root of multiplicity 2, then `roots` looks something like [2, 2, 2, 3, 3]. The roots can appear in any order.

If the returned coefficients are c , then

$$p(x) = c_0 + c_1 * He_1(x) + \dots + c_n * He_n(x)$$

The coefficient of the last term is not generally 1 for monic polynomials in HermiteE form.

Parameters

roots

[array_like] Sequence containing the roots.

Returns

out

[ndarray] 1-D array of coefficients. If all roots are real then `out` is a real array, if some of the roots are complex, then `out` is complex even if all the coefficients in the result are real (see Examples below).

See also:

`numpy.polynomial.polynomial.polyfromroots`
`numpy.polynomial.legendre.legfromroots`
`numpy.polynomial.laguerre.lagfromroots`
`numpy.polynomial.hermite.hermfromroots`
`numpy.polynomial.chebyshev.chebfromroots`

Examples

```
>>> from numpy.polynomial.hermite_e import hermefromroots, hermeval
>>> coef = hermefromroots((-1, 0, 1))
>>> hermeval((-1, 0, 1), coef)
array([0., 0., 0.])
>>> coef = hermefromroots((-1j, 1j))
>>> hermeval((-1j, 1j), coef)
array([0.+0.j, 0.+0.j])
```

`polynomial.hermite_e.hermroots(c)`

Compute the roots of a HermiteE series.

Return the roots (a.k.a. “zeros”) of the polynomial

$$p(x) = \sum_i c[i] * He_i(x).$$

Parameters

c
[1-D array_like] 1-D array of coefficients.

Returns

out
[ndarray] Array of the roots of the series. If all the roots are real, then *out* is also real, otherwise it is complex.

See also:

`numpy.polynomial.polynomial.polyroots`
`numpy.polynomial.legendre.legroots`
`numpy.polynomial.laguerre.lagroots`
`numpy.polynomial.hermite.hermroots`
`numpy.polynomial.chebyshev.chebroots`

Notes

The root estimates are obtained as the eigenvalues of the companion matrix, Roots far from the origin of the complex plane may have large errors due to the numerical instability of the series for such values. Roots with multiplicity greater than 1 will also show larger errors as the value of the series near such points is relatively insensitive to errors in the roots. Isolated roots near the origin can be improved by a few iterations of Newton’s method.

The HermiteE series basis polynomials aren’t powers of x so the results of this function may seem unintuitive.

Examples

```
>>> from numpy.polynomial.hermite_e import hermeroots, hermefromroots
>>> coef = hermefromroots([-1, 0, 1])
>>> coef
array([0., 2., 0., 1.])
>>> hermeroots(coef)
array([-1., 0., 1.]) # may vary
```

`polynomial.hermite_e.hermevander(x, deg)`

Pseudo-Vandermonde matrix of given degree.

Returns the pseudo-Vandermonde matrix of degree *deg* and sample points *x*. The pseudo-Vandermonde matrix is defined by

$$V[..., i] = He_i(x),$$

where $0 \leq i \leq \text{deg}$. The leading indices of *V* index the elements of *x* and the last index is the degree of the HermiteE polynomial.

If *c* is a 1-D array of coefficients of length $n + 1$ and *V* is the array $V = \text{hermevander}(x, n)$, then `np.dot(V, c)` and `hermeval(x, c)` are the same up to roundoff. This equivalence is useful both for least squares fitting and for the evaluation of a large number of HermiteE series of the same degree and sample points.

Parameters

x

[array_like] Array of points. The dtype is converted to float64 or complex128 depending on whether any of the elements are complex. If *x* is scalar it is converted to a 1-D array.

deg

[int] Degree of the resulting matrix.

Returns

vander

[ndarray] The pseudo-Vandermonde matrix. The shape of the returned matrix is `x.shape + (deg + 1,)`, where The last index is the degree of the corresponding HermiteE polynomial. The dtype will be the same as the converted *x*.

Examples

```
>>> import numpy as np
>>> from numpy.polynomial.hermite_e import hermevander
>>> x = np.array([-1, 0, 1])
>>> hermevander(x, 3)
array([[ 1., -1., 0., 2.],
       [ 1., 0., -1., -0.],
       [ 1., 1., 0., -2.]])
```

`polynomial.hermite_e.hermevander2d(x, y, deg)`

Pseudo-Vandermonde matrix of given degrees.

Returns the pseudo-Vandermonde matrix of degrees *deg* and sample points (x, y) . The pseudo-Vandermonde matrix is defined by

$$V[...,(deg[1] + 1) * i + j] = He_i(x) * He_j(y),$$

where $0 \leq i \leq \text{deg}[0]$ and $0 \leq j \leq \text{deg}[1]$. The leading indices of V index the points (x, y) and the last index encodes the degrees of the HermiteE polynomials.

If $V = \text{hermevander2d}(x, y, [\text{xdeg}, \text{ydeg}])$, then the columns of V correspond to the elements of a 2-D coefficient array c of shape $(\text{xdeg} + 1, \text{ydeg} + 1)$ in the order

$$c_{00}, c_{01}, c_{02}, \dots, c_{10}, c_{11}, c_{12}, \dots$$

and $\text{np.dot}(V, c.\text{flat})$ and $\text{hermeval2d}(x, y, c)$ will be the same up to roundoff. This equivalence is useful both for least squares fitting and for the evaluation of a large number of 2-D HermiteE series of the same degrees and sample points.

Parameters

x, y

[array_like] Arrays of point coordinates, all of the same shape. The dtypes will be converted to either float64 or complex128 depending on whether any of the elements are complex. Scalars are converted to 1-D arrays.

deg

[list of ints] List of maximum degrees of the form $[x_deg, y_deg]$.

Returns

vander2d

[ndarray] The shape of the returned matrix is $x.\text{shape} + (\text{order},)$, where $\text{order} = (\text{deg}[0] + 1) * (\text{deg}[1] + 1)$. The dtype will be the same as the converted x and y .

See also:

[*hermevander*](#), [*hermevander3d*](#), [*hermeval2d*](#), [*hermeval3d*](#)

`polynomial.hermite_e.hermevander3d(x, y, z, deg)`

Pseudo-Vandermonde matrix of given degrees.

Returns the pseudo-Vandermonde matrix of degrees deg and sample points (x, y, z) . If l, m, n are the given degrees in x, y, z , then Hehe pseudo-Vandermonde matrix is defined by

$$V[\dots, (m+1)(n+1)i + (n+1)j + k] = He_i(x) * He_j(y) * He_k(z),$$

where $0 \leq i \leq l, 0 \leq j \leq m$, and $0 \leq k \leq n$. The leading indices of V index the points (x, y, z) and the last index encodes the degrees of the HermiteE polynomials.

If $V = \text{hermevander3d}(x, y, z, [\text{xdeg}, \text{ydeg}, \text{zdeg}])$, then the columns of V correspond to the elements of a 3-D coefficient array c of shape $(\text{xdeg} + 1, \text{ydeg} + 1, \text{zdeg} + 1)$ in the order

$$c_{000}, c_{001}, c_{002}, \dots, c_{010}, c_{011}, c_{012}, \dots$$

and $\text{np.dot}(V, c.\text{flat})$ and $\text{hermeval3d}(x, y, z, c)$ will be the same up to roundoff. This equivalence is useful both for least squares fitting and for the evaluation of a large number of 3-D HermiteE series of the same degrees and sample points.

Parameters

x, y, z

[array_like] Arrays of point coordinates, all of the same shape. The dtypes will be converted to either float64 or complex128 depending on whether any of the elements are complex. Scalars are converted to 1-D arrays.

deg

[list of ints] List of maximum degrees of the form $[x_deg, y_deg, z_deg]$.

Returns**vander3d**

[ndarray] The shape of the returned matrix is `x.shape + (order,)`, where `order = (deg[0] + 1) * (deg[1] + 1) * (deg[2] + 1)`. The dtype will be the same as the converted `x`, `y`, and `z`.

See also:

[*hermevander*](#), [*hermevander3d*](#), [*hermeval2d*](#), [*hermeval3d*](#)

`polynomial.hermite_e.hermegauss(deg)`

Gauss-HermiteE quadrature.

Computes the sample points and weights for Gauss-HermiteE quadrature. These sample points and weights will correctly integrate polynomials of degree $2 * deg - 1$ or less over the interval $[-\infty, \infty]$ with the weight function $f(x) = \exp(-x^2/2)$.

Parameters**deg**

[int] Number of sample points and weights. It must be ≥ 1 .

Returns**x**

[ndarray] 1-D ndarray containing the sample points.

y

[ndarray] 1-D ndarray containing the weights.

Notes

The results have only been tested up to degree 100, higher degrees may be problematic. The weights are determined by using the fact that

$$w_k = c / (He'_n(x_k) * He_{n-1}(x_k))$$

where c is a constant independent of k and x_k is the k 'th root of He_n , and then scaling the results to get the right value when integrating 1.

`polynomial.hermite_e.hermeweight(x)`

Weight function of the Hermite_e polynomials.

The weight function is $\exp(-x^2/2)$ and the interval of integration is $[-\infty, \infty]$. the HermiteE polynomials are orthogonal, but not normalized, with respect to this weight function.

Parameters**x**

[array_like] Values at which the weight function will be computed.

Returns**w**

[ndarray] The weight function at x .

`polynomial.hermite_e.hermecompanion(c)`

Return the scaled companion matrix of *c*.

The basis polynomials are scaled so that the companion matrix is symmetric when *c* is a HermiteE basis polynomial. This provides better eigenvalue estimates than the unscaled case and for basis polynomials the eigenvalues are guaranteed to be real if `numpy.linalg.eigvalsh` is used to obtain them.

Parameters

c
[array_like] 1-D array of HermiteE series coefficients ordered from low to high degree.

Returns

mat
[ndarray] Scaled companion matrix of dimensions (deg, deg).

`polynomial.hermite_e.hermefit(x, y, deg, rcond=None, full=False, w=None)`

Least squares fit of Hermite series to data.

Return the coefficients of a HermiteE series of degree *deg* that is the least squares fit to the data values *y* given at points *x*. If *y* is 1-D the returned coefficients will also be 1-D. If *y* is 2-D multiple fits are done, one for each column of *y*, and the resulting coefficients are stored in the corresponding columns of a 2-D return. The fitted polynomial(s) are in the form

$$p(x) = c_0 + c_1 * He_1(x) + \dots + c_n * He_n(x),$$

where *n* is *deg*.

Parameters

x
[array_like, shape (M,)] x-coordinates of the M sample points (`x[i]`, `y[i]`).

y
[array_like, shape (M,) or (M, K)] y-coordinates of the sample points. Several data sets of sample points sharing the same x-coordinates can be fitted at once by passing in a 2D-array that contains one dataset per column.

deg
[int or 1-D array_like] Degree(s) of the fitting polynomials. If *deg* is a single integer all terms up to and including the *deg*'th term are included in the fit. For NumPy versions $\geq 1.11.0$ a list of integers specifying the degrees of the terms to include may be used instead.

rcond
[float, optional] Relative condition number of the fit. Singular values smaller than this relative to the largest singular value will be ignored. The default value is `len(x)*eps`, where `eps` is the relative precision of the float type, about $2e-16$ in most cases.

full
[bool, optional] Switch determining nature of return value. When it is False (the default) just the coefficients are returned, when True diagnostic information from the singular value decomposition is also returned.

w
[array_like, shape (M,), optional] Weights. If not None, the weight `w[i]` applies to the unsquared residual `y[i] - y_hat[i]` at `x[i]`. Ideally the weights are chosen so that the errors of the products `w[i]*y[i]` all have the same variance. When using inverse-variance weighting, use `w[i] = 1/sigma(y[i])`. The default value is None.

Returns

coef

[ndarray, shape (M,) or (M, K)] Hermite coefficients ordered from low to high. If *y* was 2-D, the coefficients for the data in column *k* of *y* are in column *k*.

[residuals, rank, singular_values, rcond]

[list] These values are only returned if `full == True`

- residuals – sum of squared residuals of the least squares fit
- rank – the numerical rank of the scaled Vandermonde matrix
- singular_values – singular values of the scaled Vandermonde matrix
- rcond – value of *rcond*.

For more details, see `numpy.linalg.lstsq`.

Warns**RankWarning**

The rank of the coefficient matrix in the least-squares fit is deficient. The warning is only raised if `full = False`. The warnings can be turned off by

```
>>> import warnings
>>> warnings.simplefilter('ignore', np.exceptions.RankWarning)
```

See also:

`numpy.polynomial.chebyshev.chebfit`
`numpy.polynomial.legendre.legfit`
`numpy.polynomial.polynomial.polyfit`
`numpy.polynomial.hermite.hermfit`
`numpy.polynomial.laguerre.lagfit`
`hermeval`

Evaluates a Hermite series.

`hermevander`

pseudo Vandermonde matrix of Hermite series.

`hermeweight`

HermiteE weight function.

`numpy.linalg.lstsq`

Computes a least-squares fit from the matrix.

`scipy.interpolate.UnivariateSpline`

Computes spline fits.

Notes

The solution is the coefficients of the HermiteE series *p* that minimizes the sum of the weighted squared errors

$$E = \sum_j w_j^2 * |y_j - p(x_j)|^2,$$

where the *w_j* are the weights. This problem is solved by setting up the (typically) overdetermined matrix equation

$$V(x) * c = w * y,$$

where *V* is the pseudo Vandermonde matrix of *x*, the elements of *c* are the coefficients to be solved for, and the elements of *y* are the observed values. This equation is then solved using the singular value decomposition of *V*.

If some of the singular values of V are so small that they are neglected, then a *RankWarning* will be issued. This means that the coefficient values may be poorly determined. Using a lower order fit will usually get rid of the warning. The *rcond* parameter can also be set to a value smaller than its default, but the resulting fit may be spurious and have large contributions from roundoff error.

Fits using HermiteE series are probably most useful when the data can be approximated by $\sqrt{w(x)} \cdot p(x)$, where $w(x)$ is the HermiteE weight. In that case the weight $\sqrt{w(x[i])}$ should be used together with data values $y[i]/\sqrt{w(x[i])}$. The weight function is available as *hermeweight*.

Examples

```
>>> import numpy as np
>>> from numpy.polynomial.hermite_e import hermitefit, hermeval
>>> x = np.linspace(-10, 10)
>>> rng = np.random.default_rng()
>>> err = rng.normal(scale=1./10, size=len(x))
>>> y = hermeval(x, [1, 2, 3]) + err
>>> hermitefit(x, y, 2)
array([1.02284196, 2.00032805, 2.99978457]) # may vary
```

`polynomial.hermite_e.hermetrim(c, tol=0)`

Remove “small” “trailing” coefficients from a polynomial.

“Small” means “small in absolute value” and is controlled by the parameter *tol*; “trailing” means highest order coefficient(s), e.g., in $[0, 1, 1, 0, 0]$ (which represents $0 + x + x^2 + 0x^3 + 0x^4$) both the 3-rd and 4-th order coefficients would be “trimmed.”

Parameters

c

[array_like] 1-d array of coefficients, ordered from lowest order to highest.

tol

[number, optional] Trailing (i.e., highest order) elements with absolute value less than or equal to *tol* (default value is zero) are removed.

Returns

trimmed

[ndarray] 1-d array with trailing zeros removed. If the resulting series would be empty, a series containing a single zero is returned.

Raises

ValueError

If *tol* < 0

Examples

```
>>> from numpy.polynomial import polyutils as pu
>>> pu.trimcoef((0,0,3,0,5,0,0))
array([0., 0., 3., 0., 5.])
>>> pu.trimcoef((0,0,1e-3,0,1e-5,0,0),1e-3) # item == tol is trimmed
array([0.])
>>> i = complex(0,1) # works for complex
>>> pu.trimcoef((3e-4,1e-3*(1-i),5e-4,2e-5*(1+i)), 1e-3)
array([0.0003+0.j, 0.001 -0.001j])
```

`polynomial.hermite_e.hermeline` (*off*, *scl*)

Hermite series whose graph is a straight line.

Parameters

off, scl

[scalars] The specified line is given by $\text{off} + \text{scl} \cdot x$.

Returns

y

[ndarray] This module's representation of the Hermite series for $\text{off} + \text{scl} \cdot x$.

See also:

`numpy.polynomial.polynomial.polyline`
`numpy.polynomial.chebyshev.chebline`
`numpy.polynomial.legendre.legline`
`numpy.polynomial.laguerre.lagline`
`numpy.polynomial.hermite.hermline`

Examples

```
>>> from numpy.polynomial.hermite_e import hermline
>>> from numpy.polynomial.hermite_e import hermline, hermeval
>>> hermeval(0,hermline(3, 2))
3.0
>>> hermeval(1,hermline(3, 2))
5.0
```

`polynomial.hermite_e.herme2poly` (*c*)

Convert a Hermite series to a polynomial.

Convert an array representing the coefficients of a Hermite series, ordered from lowest degree to highest, to an array of the coefficients of the equivalent polynomial (relative to the “standard” basis) ordered from lowest to highest degree.

Parameters

c

[array_like] 1-D array containing the Hermite series coefficients, ordered from lowest order term to highest.

Returns

pol

[ndarray] 1-D array containing the coefficients of the equivalent polynomial (relative to the “standard” basis) ordered from lowest order term to highest.

See also:

[*poly2herme*](#)

Notes

The easy way to do conversions between polynomial basis sets is to use the convert method of a class instance.

Examples

```
>>> from numpy.polynomial.hermite_e import herme2poly
>>> herme2poly([ 2., 10., 2., 3.])
array([0., 1., 2., 3.]
```

`polynomial.hermite_e.poly2herme` (*pol*)

Convert a polynomial to a Hermite series.

Convert an array representing the coefficients of a polynomial (relative to the “standard” basis) ordered from lowest degree to highest, to an array of the coefficients of the equivalent Hermite series, ordered from lowest to highest degree.

Parameters

pol

[array_like] 1-D array containing the polynomial coefficients

Returns

c

[ndarray] 1-D array containing the coefficients of the equivalent Hermite series.

See also:

[*herme2poly*](#)

Notes

The easy way to do conversions between polynomial basis sets is to use the convert method of a class instance.

Examples

```
>>> import numpy as np
>>> from numpy.polynomial.hermite_e import poly2herme
>>> poly2herme(np.arange(4))
array([ 2., 10., 2., 3.]
```

`numpy.polynomial`

Laguerre Series (`numpy.polynomial.laguerre`)

This module provides a number of objects (mostly functions) useful for dealing with Laguerre series, including a *Laguerre* class that encapsulates the usual arithmetic operations. (General information on how this module represents and works with such polynomials is in the docstring for its “parent” sub-package, `numpy.polynomial`).

Classes

<code>Laguerre(coef[, domain, window, symbol])</code>	A Laguerre series class.
---	--------------------------

class `numpy.polynomial.laguerre.Laguerre` (*coef*, *domain=None*, *window=None*, *symbol='x'*)

A Laguerre series class.

The Laguerre class provides the standard Python numerical methods ‘+’, ‘-’, ‘*’, ‘/’, ‘%’, ‘divmod’, ‘**’, and ‘()’ as well as the attributes and methods listed below.

Parameters

coef

[array_like] Laguerre coefficients in order of increasing degree, i.e. (1, 2, 3) gives $1*L_0(x) + 2*L_1(x) + 3*L_2(x)$.

domain

[(2,) array_like, optional] Domain to use. The interval `[domain[0], domain[1]]` is mapped to the interval `[window[0], window[1]]` by shifting and scaling. The default value is `[0., 1.]`.

window

[(2,) array_like, optional] Window, see `domain` for its use. The default value is `[0., 1.]`.

symbol

[str, optional] Symbol used to represent the independent variable in string representations of the polynomial expression, e.g. for printing. The symbol must be a valid Python identifier. Default value is ‘x’.

New in version 1.24.

Attributes

symbol

Methods

<code>__call__(arg)</code>	Call self as a function.
<code>basis(deg[, domain, window, symbol])</code>	Series basis polynomial of degree <i>deg</i> .
<code>cast(series[, domain, window])</code>	Convert series to series of this class.
<code>convert([domain, kind, window])</code>	Convert series to a different kind and/or domain and/or window.
<code>copy()</code>	Return a copy.
<code>cutdeg(deg)</code>	Truncate series to the given degree.
<code>degree()</code>	The degree of the series.
<code>deriv([m])</code>	Differentiate.
<code>fit(x, y, deg[, domain, rcond, full, w, ...])</code>	Least squares fit to data.
<code>fromroots(roots[, domain, window, symbol])</code>	Return series instance that has the specified roots.
<code>has_samecoef(other)</code>	Check if coefficients match.
<code>has_samedomain(other)</code>	Check if domains match.
<code>has_sametype(other)</code>	Check if types match.
<code>has_samewindow(other)</code>	Check if windows match.
<code>identity([domain, window, symbol])</code>	Identity function.
<code>integ([m, k, lbnd])</code>	Integrate.
<code>linspace([n, domain])</code>	Return x, y values at equally spaced points in domain.
<code>mapparms()</code>	Return the mapping parameters.
<code>roots()</code>	Return the roots of the series polynomial.
<code>trim([tol])</code>	Remove trailing coefficients
<code>truncate(size)</code>	Truncate series to length <i>size</i> .

method

`polynomial.laguerre.Laguerre.__call__(arg)`

Call self as a function.

method

classmethod `polynomial.laguerre.Laguerre.basis(deg, domain=None, window=None, symbol='x')`

Series basis polynomial of degree *deg*.

Returns the series representing the basis polynomial of degree *deg*.

Parameters

deg

[int] Degree of the basis polynomial for the series. Must be ≥ 0 .

domain

[{None, array_like}, optional] If given, the array must be of the form `[beg, end]`, where *beg* and *end* are the endpoints of the domain. If None is given then the class domain is used. The default is None.

window

[{None, array_like}, optional] If given, the resulting array must be if the form `[beg, end]`, where *beg* and *end* are the endpoints of the window. If None is given then the class window is used. The default is None.

symbol

[str, optional] Symbol representing the independent variable. Default is 'x'.

Returns

new_series

[series] A series with the coefficient of the *deg* term set to one and all others zero.

method

classmethod `polynomial.laguerre.Laguerre.cast` (*series*, *domain=None*, *window=None*)

Convert series to series of this class.

The *series* is expected to be an instance of some polynomial series of one of the types supported by the `numpy.polynomial` module, but could be some other class that supports the `convert` method.

Parameters**series**

[series] The series instance to be converted.

domain

[None, array_like], optional] If given, the array must be of the form `[beg, end]`, where `beg` and `end` are the endpoints of the domain. If `None` is given then the class domain is used. The default is `None`.

window

[None, array_like], optional] If given, the resulting array must be of the form `[beg, end]`, where `beg` and `end` are the endpoints of the window. If `None` is given then the class window is used. The default is `None`.

Returns**new_series**

[series] A series of the same kind as the calling class and equal to *series* when evaluated.

See also:***convert***

similar instance method

method

`polynomial.laguerre.Laguerre.convert` (*domain=None*, *kind=None*, *window=None*)

Convert series to a different kind and/or domain and/or window.

Parameters**domain**

[array_like, optional] The domain of the converted series. If the value is `None`, the default domain of *kind* is used.

kind

[class, optional] The polynomial series type class to which the current instance should be converted. If *kind* is `None`, then the class of the current instance is used.

window

[array_like, optional] The window of the converted series. If the value is `None`, the default window of *kind* is used.

Returns**new_series**

[series] The returned class can be of different type than the current instance and/or have a different domain and/or different window.

Notes

Conversion between domains and class types can result in numerically ill defined series.

method

```
polynomial.laguerre.Laguerre.copy()
```

Return a copy.

Returns

new_series

[series] Copy of self.

method

```
polynomial.laguerre.Laguerre.cutdeg(deg)
```

Truncate series to the given degree.

Reduce the degree of the series to *deg* by discarding the high order terms. If *deg* is greater than the current degree a copy of the current series is returned. This can be useful in least squares where the coefficients of the high degree terms may be very small.

Parameters

deg

[non-negative int] The series is reduced to degree *deg* by discarding the high order terms. The value of *deg* must be a non-negative integer.

Returns

new_series

[series] New instance of series with reduced degree.

method

```
polynomial.laguerre.Laguerre.degree()
```

The degree of the series.

Returns

degree

[int] Degree of the series, one less than the number of coefficients.

Examples

Create a polynomial object for $1 + 7x + 4x^2$:

```

>>> np.polynomial.set_default_printstyle("unicode")
>>> poly = np.polynomial.Polynomial([1, 7, 4])
>>> print(poly)
1.0 + 7.0·x + 4.0·x2
>>> poly.degree()
2

```

Note that this method does not check for non-zero coefficients. You must trim the polynomial to remove any trailing zeroes:

```
>>> poly = np.polynomial.Polynomial([1, 7, 0])
>>> print(poly)
1.0 + 7.0·x + 0.0·x2
>>> poly.degree()
2
>>> poly.trim().degree()
1
```

method

`polynomial.laguerre.Laguerre.deriv(m=1)`

Differentiate.

Return a series instance of that is the derivative of the current series.

Parameters

m

[non-negative int] Find the derivative of order *m*.

Returns

new_series

[series] A new series representing the derivative. The domain is the same as the domain of the differentiated series.

method

classmethod `polynomial.laguerre.Laguerre.fit(x, y, deg, domain=None, rcond=None, full=False, w=None, window=None, symbol='x')`

Least squares fit to data.

Return a series instance that is the least squares fit to the data *y* sampled at *x*. The domain of the returned instance can be specified and this will often result in a superior fit with less chance of ill conditioning.

Parameters

x

[array_like, shape (M,)] x-coordinates of the M sample points (*x*[*i*], *y*[*i*]).

y

[array_like, shape (M,)] y-coordinates of the M sample points (*x*[*i*], *y*[*i*]).

deg

[int or 1-D array_like] Degree(s) of the fitting polynomials. If *deg* is a single integer all terms up to and including the *deg*'th term are included in the fit. For NumPy versions $\geq 1.11.0$ a list of integers specifying the degrees of the terms to include may be used instead.

domain

[{None, [beg, end], []}, optional] Domain to use for the returned series. If *None*, then a minimal domain that covers the points *x* is chosen. If [] the class domain is used. The default value was the class domain in NumPy 1.4 and *None* in later versions. The [] option was added in numpy 1.5.0.

rcond

[float, optional] Relative condition number of the fit. Singular values smaller than this relative to the largest singular value will be ignored. The default value is `len(x)*eps`, where *eps* is the relative precision of the float type, about 2e-16 in most cases.

full

[bool, optional] Switch determining nature of return value. When it is False (the default) just the coefficients are returned, when True diagnostic information from the singular value decomposition is also returned.

w

[array_like, shape (M,), optional] Weights. If not None, the weight $w[i]$ applies to the unsquared residual $y[i] - \hat{y}[i]$ at $x[i]$. Ideally the weights are chosen so that the errors of the products $w[i] * y[i]$ all have the same variance. When using inverse-variance weighting, use $w[i] = 1/\text{sigma}(y[i])$. The default value is None.

window

[[[beg, end]], optional] Window to use for the returned series. The default value is the default class domain

symbol

[str, optional] Symbol representing the independent variable. Default is 'x'.

Returns**new_series**

[series] A series that represents the least squares fit to the data and has the domain and window specified in the call. If the coefficients for the unscaled and unshifted basis polynomials are of interest, do `new_series.convert().coef`.

[resid, rank, sv, rcond]

[list] These values are only returned if `full == True`

- resid – sum of squared residuals of the least squares fit
- rank – the numerical rank of the scaled Vandermonde matrix
- sv – singular values of the scaled Vandermonde matrix
- rcond – value of *rcond*.

For more details, see [linalg.lstsq](#).

method

classmethod `polynomial.laguerre.Laguerre.fromroots` (*roots*, *domain*=[], *window*=None, *symbol*='x')

Return series instance that has the specified roots.

Returns a series representing the product $(x - r[0]) * (x - r[1]) * \dots * (x - r[n-1])$, where *r* is a list of roots.

Parameters**roots**

[array_like] List of roots.

domain

[[], None, array_like], optional] Domain for the resulting series. If None the domain is the interval from the smallest root to the largest. If [] the domain is the class domain. The default is [].

window

[None, array_like], optional] Window for the returned series. If None the class window is used. The default is None.

symbol

[str, optional] Symbol representing the independent variable. Default is 'x'.

Returns**new_series**

[series] Series with the specified roots.

method

`polynomial.laguerre.Laguerre.has_samecoef (other)`

Check if coefficients match.

Parameters**other**

[class instance] The other class must have the `coef` attribute.

Returns**bool**

[boolean] True if the coefficients are the same, False otherwise.

method

`polynomial.laguerre.Laguerre.has_samedomain (other)`

Check if domains match.

Parameters**other**

[class instance] The other class must have the `domain` attribute.

Returns**bool**

[boolean] True if the domains are the same, False otherwise.

method

`polynomial.laguerre.Laguerre.has_sametype (other)`

Check if types match.

Parameters**other**

[object] Class instance.

Returns**bool**

[boolean] True if other is same class as self

method

`polynomial.laguerre.Laguerre.has_samewindow (other)`

Check if windows match.

Parameters**other**

[class instance] The other class must have the `window` attribute.

Returns**bool**

[boolean] True if the windows are the same, False otherwise.

method

classmethod `polynomial.laguerre.Laguerre.identity` (*domain=None, window=None, symbol='x'*)

Identity function.

If p is the returned series, then $p(x) == x$ for all values of x .

Parameters

domain

[None, array_like], optional] If given, the array must be of the form `[beg, end]`, where `beg` and `end` are the endpoints of the domain. If `None` is given then the class domain is used. The default is `None`.

window

[None, array_like], optional] If given, the resulting array must be if the form `[beg, end]`, where `beg` and `end` are the endpoints of the window. If `None` is given then the class window is used. The default is `None`.

symbol

[str, optional] Symbol representing the independent variable. Default is `'x'`.

Returns

new_series

[series] Series of representing the identity.

method

`polynomial.laguerre.Laguerre.integ` (*m=1, k=[], lbnd=None*)

Integrate.

Return a series instance that is the definite integral of the current series.

Parameters

m

[non-negative int] The number of integrations to perform.

k

[array_like] Integration constants. The first constant is applied to the first integration, the second to the second, and so on. The list of values must less than or equal to m in length and any missing values are set to zero.

lbnd

[Scalar] The lower bound of the definite integral.

Returns

new_series

[series] A new series representing the integral. The domain is the same as the domain of the integrated series.

method

`polynomial.laguerre.Laguerre.linspace` (*n=100, domain=None*)

Return x, y values at equally spaced points in domain.

Returns the x, y values at n linearly spaced points across the domain. Here y is the value of the polynomial at the points x . By default the domain is the same as that of the series instance. This method is intended mostly as a plotting aid.

Parameters

n

[int, optional] Number of point pairs to return. The default value is 100.

domain

[{None, array_like}, optional] If not None, the specified domain is used instead of that of the calling instance. It should be of the form `[beg, end]`. The default is None which case the class domain is used.

Returns**x, y**

[ndarray] x is equal to `linspace(self.domain[0], self.domain[1], n)` and y is the series evaluated at element of x.

method

`polynomial.laguerre.Laguerre.mapparms()`

Return the mapping parameters.

The returned values define a linear map `off + scl*x` that is applied to the input arguments before the series is evaluated. The map depends on the `domain` and `window`; if the current `domain` is equal to the `window` the resulting map is the identity. If the coefficients of the series instance are to be used by themselves outside this class, then the linear function must be substituted for the `x` in the standard representation of the base polynomials.

Returns**off, scl**

[float or complex] The mapping function is defined by `off + scl*x`.

Notes

If the current domain is the interval `[l1, r1]` and the window is `[l2, r2]`, then the linear mapping function `L` is defined by the equations:

$$\begin{aligned} L(l1) &= l2 \\ L(r1) &= r2 \end{aligned}$$

method

`polynomial.laguerre.Laguerre.roots()`

Return the roots of the series polynomial.

Compute the roots for the series. Note that the accuracy of the roots decreases the further outside the domain they lie.

Returns**roots**

[ndarray] Array containing the roots of the series.

method

`polynomial.laguerre.Laguerre.trim(tol=0)`

Remove trailing coefficients

Remove trailing coefficients until a coefficient is reached whose absolute value greater than `tol` or the beginning of the series is reached. If all the coefficients would be removed the series is set to `[0]`. A new series instance is returned with the new coefficients. The current instance remains unchanged.

Parameters

tol
[non-negative number.] All trailing coefficients less than *tol* will be removed.

Returns

new_series
[series] New instance of series with trimmed coefficients.

method

`polynomial.laguerre.Laguerre.truncate` (*size*)

Truncate series to length *size*.

Reduce the series to length *size* by discarding the high degree terms. The value of *size* must be a positive integer. This can be useful in least squares where the coefficients of the high degree terms may be very small.

Parameters

size
[positive int] The series is reduced to length *size* by discarding the high degree terms. The value of *size* must be a positive integer.

Returns

new_series
[series] New instance of series with truncated coefficients.

Constants

<i>lagdomain</i>	<code>ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None)</code>
<i>lagzero</i>	<code>ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None)</code>
<i>lagone</i>	<code>ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None)</code>
<i>lagx</i>	<code>ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None)</code>

`polynomial.laguerre.lagdomain = array([0., 1.])`

`ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None) –`

`ndarray(shape, dtype=np.float64, buffer=None, offset=0, strides=None, order=None)`

An array object represents a multidimensional, homogeneous array of fixed-size items. An associated data-type object describes the format of each element in the array (its byte-order, how many bytes it occupies in memory, whether it is an integer, a floating point number, or something else, etc.)

Arrays should be constructed using *array*, *zeros* or *empty* (refer to the See Also section below). The parameters given here refer to a low-level method (*ndarray(...)*) for instantiating an array.

For more information, refer to the *numpy* module and examine the methods and attributes of an array.

Parameters

(for the `__new__` method; see Notes below)

shape
[tuple of ints] Shape of created array.

dtype

[data-type, optional] Any object that can be interpreted as a numpy data type. Default is `numpy.float64`.

buffer

[object exposing buffer interface, optional] Used to fill the array with data.

offset

[int, optional] Offset of array data in buffer.

strides

[tuple of ints, optional] Strides of data in memory.

order

[{'C', 'F'}, optional] Row-major (C-style) or column-major (Fortran-style) order.

Attributes**T**

[ndarray] Transpose of the array.

data

[buffer] The array's elements, in memory.

dtype

[dtype object] Describes the format of the elements in the array.

flags

[dict] Dictionary containing information related to memory use, e.g., 'C_CONTIGUOUS', 'OWNDATA', 'WRITEABLE', etc.

flat

[numpy.flatiter object] Flattened version of the array as an iterator. The iterator allows assignments, e.g., `x.flat = 3` (See `ndarray.flat` for assignment examples; TODO).

imag

[ndarray] Imaginary part of the array.

real

[ndarray] Real part of the array.

size

[int] Number of elements in the array.

itemsize

[int] The memory use of each array element in bytes.

nbytes

[int] The total number of bytes required to store the array data, i.e., `itemsize * size`.

ndim

[int] The array's number of dimensions.

shape

[tuple of ints] Shape of the array.

strides

[tuple of ints] The step-size required to move from one element to the next in memory. For example, a contiguous `(3, 4)` array of type `int16` in C-order has strides `(8, 2)`. This implies that to move from element to element in memory requires jumps of 2 bytes. To move from row-to-row, one needs to jump 8 bytes at a time (`2 * 4`).

ctypes

[ctypes object] Class containing properties of the array needed for interaction with ctypes.

base

[ndarray] If the array is a view into another array, that array is its *base* (unless that array is also a view). The *base* array is where the array data is actually stored.

See also:**array**

Construct an array.

zeros

Create an array, each element of which is zero.

empty

Create an array, but leave its allocated memory unchanged (i.e., it contains “garbage”).

dtype

Create a data-type.

numpy.typing.NDArray

An ndarray alias *generic* w.r.t. its *dtype.type*.

Notes

There are two modes of creating an array using `__new__`:

1. If *buffer* is None, then only *shape*, *dtype*, and *order* are used.
2. If *buffer* is an object exposing the buffer interface, then all keywords are interpreted.

No `__init__` method is needed because the array is fully initialized after the `__new__` method.

Examples

These examples illustrate the low-level *ndarray* constructor. Refer to the *See Also* section above for easier ways of constructing an ndarray.

First mode, *buffer* is None:

```
>>> import numpy as np
>>> np.ndarray(shape=(2,2), dtype=np.float64, order='F')
array([[0.0e+000, 0.0e+000], # random
       [      nan, 2.5e-323]])
```

Second mode:

```
>>> np.ndarray((2,), buffer=np.array([1,2,3]),
...           offset=np.int_.itemsize,
...           dtype=np.int_) # offset = 1*itemsize, i.e. skip first element
array([2, 3])
```

```
polynomial.laguerre.lagzero = array([0])
```

```
ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None) –
```

```
ndarray(shape, dtype=np.float64, buffer=None, offset=0, strides=None, order=None)
```

An array object represents a multidimensional, homogeneous array of fixed-size items. An associated data-type object describes the format of each element in the array (its byte-order, how many bytes it occupies in memory, whether it is an integer, a floating point number, or something else, etc.)

Arrays should be constructed using `array`, `zeros` or `empty` (refer to the See Also section below). The parameters given here refer to a low-level method (`ndarray(...)`) for instantiating an array.

For more information, refer to the `numpy` module and examine the methods and attributes of an array.

Parameters

(for the `__new__` method; see Notes below)

shape

[tuple of ints] Shape of created array.

dtype

[data-type, optional] Any object that can be interpreted as a numpy data type. Default is `numpy.float64`.

buffer

[object exposing buffer interface, optional] Used to fill the array with data.

offset

[int, optional] Offset of array data in buffer.

strides

[tuple of ints, optional] Strides of data in memory.

order

[[‘C’, ‘F’], optional] Row-major (C-style) or column-major (Fortran-style) order.

Attributes

T

[ndarray] Transpose of the array.

data

[buffer] The array’s elements, in memory.

dtype

[dtype object] Describes the format of the elements in the array.

flags

[dict] Dictionary containing information related to memory use, e.g., ‘C_CONTIGUOUS’, ‘OWNDATA’, ‘WRITEABLE’, etc.

flat

[numpy.flatiter object] Flattened version of the array as an iterator. The iterator allows assignments, e.g., `x.flat = 3` (See `ndarray.flat` for assignment examples; TODO).

imag

[ndarray] Imaginary part of the array.

real

[ndarray] Real part of the array.

size

[int] Number of elements in the array.

itemsize

[int] The memory use of each array element in bytes.

nbytes

[int] The total number of bytes required to store the array data, i.e., `itemsize * size`.

ndim

[int] The array's number of dimensions.

shape

[tuple of ints] Shape of the array.

strides

[tuple of ints] The step-size required to move from one element to the next in memory. For example, a contiguous (3, 4) array of type `int16` in C-order has strides (8, 2). This implies that to move from element to element in memory requires jumps of 2 bytes. To move from row-to-row, one needs to jump 8 bytes at a time ($2 * 4$).

ctypes

[ctypes object] Class containing properties of the array needed for interaction with ctypes.

base

[ndarray] If the array is a view into another array, that array is its *base* (unless that array is also a view). The *base* array is where the array data is actually stored.

See also:***array***

Construct an array.

zeros

Create an array, each element of which is zero.

empty

Create an array, but leave its allocated memory unchanged (i.e., it contains “garbage”).

dtype

Create a data-type.

numpy.typing.NDArray

An ndarray alias *generic* w.r.t. its *dtype.type*.

Notes

There are two modes of creating an array using `__new__`:

1. If *buffer* is None, then only *shape*, *dtype*, and *order* are used.
2. If *buffer* is an object exposing the buffer interface, then all keywords are interpreted.

No `__init__` method is needed because the array is fully initialized after the `__new__` method.

Examples

These examples illustrate the low-level *ndarray* constructor. Refer to the *See Also* section above for easier ways of constructing an ndarray.

First mode, *buffer* is None:

```
>>> import numpy as np
>>> np.ndarray(shape=(2,2), dtype=np.float64, order='F')
array([[0.0e+000, 0.0e+000], # random
       [      nan, 2.5e-323]])
```

Second mode:

```
>>> np.ndarray((2,), buffer=np.array([1,2,3]),
...           offset=np.int_().itemsize,
...           dtype=np.int_) # offset = 1*itemsize, i.e. skip first element
array([2, 3])
```

```
polynomial.laguerre.lagone = array([1])
```

```
ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None) -
```

```
ndarray(shape, dtype=np.float64, buffer=None, offset=0, strides=None, order=None)
```

An array object represents a multidimensional, homogeneous array of fixed-size items. An associated data-type object describes the format of each element in the array (its byte-order, how many bytes it occupies in memory, whether it is an integer, a floating point number, or something else, etc.)

Arrays should be constructed using *array*, *zeros* or *empty* (refer to the See Also section below). The parameters given here refer to a low-level method (*ndarray(...)*) for instantiating an array.

For more information, refer to the *numpy* module and examine the methods and attributes of an array.

Parameters

(for the `__new__` method; see Notes below)

shape

[tuple of ints] Shape of created array.

dtype

[data-type, optional] Any object that can be interpreted as a numpy data type. Default is *numpy.float64*.

buffer

[object exposing buffer interface, optional] Used to fill the array with data.

offset

[int, optional] Offset of array data in buffer.

strides

[tuple of ints, optional] Strides of data in memory.

order

[{'C', 'F'}, optional] Row-major (C-style) or column-major (Fortran-style) order.

Attributes

T

[ndarray] Transpose of the array.

data

[buffer] The array's elements, in memory.

dtype

[dtype object] Describes the format of the elements in the array.

flags

[dict] Dictionary containing information related to memory use, e.g., 'C_CONTIGUOUS', 'OWNDATA', 'WRITEABLE', etc.

flat

[numpy.flatiter object] Flattened version of the array as an iterator. The iterator allows assignments, e.g., `x.flat = 3` (See *ndarray.flat* for assignment examples; TODO).

imag

[ndarray] Imaginary part of the array.

real

[ndarray] Real part of the array.

size

[int] Number of elements in the array.

itemsize

[int] The memory use of each array element in bytes.

nbytes

[int] The total number of bytes required to store the array data, i.e., `itemsize * size`.

ndim

[int] The array's number of dimensions.

shape

[tuple of ints] Shape of the array.

strides

[tuple of ints] The step-size required to move from one element to the next in memory. For example, a contiguous (3, 4) array of type `int16` in C-order has strides (8, 2). This implies that to move from element to element in memory requires jumps of 2 bytes. To move from row-to-row, one needs to jump 8 bytes at a time (2 * 4).

ctypes

[ctypes object] Class containing properties of the array needed for interaction with ctypes.

base

[ndarray] If the array is a view into another array, that array is its *base* (unless that array is also a view). The *base* array is where the array data is actually stored.

See also:**`array`**

Construct an array.

`zeros`

Create an array, each element of which is zero.

`empty`

Create an array, but leave its allocated memory unchanged (i.e., it contains “garbage”).

`dtype`

Create a data-type.

`numpy.typing.NDArray`

An ndarray alias *generic* w.r.t. its `dtype.type`.

Notes

There are two modes of creating an array using `__new__`:

1. If *buffer* is None, then only *shape*, *dtype*, and *order* are used.
2. If *buffer* is an object exposing the buffer interface, then all keywords are interpreted.

No `__init__` method is needed because the array is fully initialized after the `__new__` method.

Examples

These examples illustrate the low-level `ndarray` constructor. Refer to the *See Also* section above for easier ways of constructing an ndarray.

First mode, *buffer* is None:

```
>>> import numpy as np
>>> np.ndarray(shape=(2,2), dtype=np.float64, order='F')
array([[0.0e+000, 0.0e+000], # random
       [      nan, 2.5e-323]])
```

Second mode:

```
>>> np.ndarray((2,), buffer=np.array([1,2,3]),
...           offset=np.int_().itemsize,
...           dtype=np.int_) # offset = 1*itemsize, i.e. skip first element
array([2, 3])
```

```
polynomial.laguerre.lagx = array([ 1, -1])
```

`ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None) -`

`ndarray(shape, dtype=np.float64, buffer=None, offset=0, strides=None, order=None)`

An array object represents a multidimensional, homogeneous array of fixed-size items. An associated data-type object describes the format of each element in the array (its byte-order, how many bytes it occupies in memory, whether it is an integer, a floating point number, or something else, etc.)

Arrays should be constructed using `array`, `zeros` or `empty` (refer to the *See Also* section below). The parameters given here refer to a low-level method (`ndarray(...)`) for instantiating an array.

For more information, refer to the `numpy` module and examine the methods and attributes of an array.

Parameters

(for the `__new__` method; see Notes below)

shape

[tuple of ints] Shape of created array.

dtype

[data-type, optional] Any object that can be interpreted as a numpy data type. Default is `numpy.float64`.

buffer

[object exposing buffer interface, optional] Used to fill the array with data.

offset

[int, optional] Offset of array data in buffer.

strides

[tuple of ints, optional] Strides of data in memory.

order

[{'C', 'F'}, optional] Row-major (C-style) or column-major (Fortran-style) order.

Attributes

T

[ndarray] Transpose of the array.

data

[buffer] The array's elements, in memory.

dtype

[dtype object] Describes the format of the elements in the array.

flags

[dict] Dictionary containing information related to memory use, e.g., 'C_CONTIGUOUS', 'OWNDATA', 'WRITEABLE', etc.

flat

[numpy.flatiter object] Flattened version of the array as an iterator. The iterator allows assignments, e.g., `x.flat = 3` (See [ndarray.flat](#) for assignment examples; TODO).

imag

[ndarray] Imaginary part of the array.

real

[ndarray] Real part of the array.

size

[int] Number of elements in the array.

itemsize

[int] The memory use of each array element in bytes.

nbytes

[int] The total number of bytes required to store the array data, i.e., `itemsize * size`.

ndim

[int] The array's number of dimensions.

shape

[tuple of ints] Shape of the array.

strides

[tuple of ints] The step-size required to move from one element to the next in memory. For example, a contiguous (3, 4) array of type `int16` in C-order has strides (8, 2). This implies that to move from element to element in memory requires jumps of 2 bytes. To move from row-to-row, one needs to jump 8 bytes at a time (2 * 4).

ctypes

[ctypes object] Class containing properties of the array needed for interaction with ctypes.

base

[ndarray] If the array is a view into another array, that array is its *base* (unless that array is also a view). The *base* array is where the array data is actually stored.

See also:**[array](#)**

Construct an array.

[zeros](#)

Create an array, each element of which is zero.

[empty](#)

Create an array, but leave its allocated memory unchanged (i.e., it contains "garbage").

[dtype](#)

Create a data-type.

[numpy.typing.NDArray](#)

An ndarray alias *generic* w.r.t. its `dtype.type`.

Notes

There are two modes of creating an array using `__new__`:

1. If *buffer* is None, then only *shape*, *dtype*, and *order* are used.
2. If *buffer* is an object exposing the buffer interface, then all keywords are interpreted.

No `__init__` method is needed because the array is fully initialized after the `__new__` method.

Examples

These examples illustrate the low-level *ndarray* constructor. Refer to the *See Also* section above for easier ways of constructing an ndarray.

First mode, *buffer* is None:

```
>>> import numpy as np
>>> np.ndarray(shape=(2,2), dtype=np.float64, order='F')
array([[0.0e+000, 0.0e+000], # random
       [      nan, 2.5e-323]])
```

Second mode:

```
>>> np.ndarray((2,), buffer=np.array([1,2,3]),
...           offset=np.int_().itemsize,
...           dtype=np.int_) # offset = 1*itemsize, i.e. skip first element
array([2, 3])
```

Arithmetic

<i>lagadd</i> (c1, c2)	Add one Laguerre series to another.
<i>lagsub</i> (c1, c2)	Subtract one Laguerre series from another.
<i>lagmulx</i> (c)	Multiply a Laguerre series by x.
<i>lagmul</i> (c1, c2)	Multiply one Laguerre series by another.
<i>lagdiv</i> (c1, c2)	Divide one Laguerre series by another.
<i>lagpow</i> (c, pow[, maxpower])	Raise a Laguerre series to a power.
<i>lagval</i> (x, c[, tensor])	Evaluate a Laguerre series at points x.
<i>lagval2d</i> (x, y, c)	Evaluate a 2-D Laguerre series at points (x, y).
<i>lagval3d</i> (x, y, z, c)	Evaluate a 3-D Laguerre series at points (x, y, z).
<i>lagvalnd</i> (pts, c)	Evaluate an N-D Laguerre series at points.
<i>laggrid2d</i> (x, y, c)	Evaluate a 2-D Laguerre series on the Cartesian product of x and y.
<i>laggrid3d</i> (x, y, z, c)	Evaluate a 3-D Laguerre series on the Cartesian product of x, y, and z.

`polynomial.laguerre.lagadd(c1, c2)`

Add one Laguerre series to another.

Returns the sum of two Laguerre series $c1 + c2$. The arguments are sequences of coefficients ordered from lowest order term to highest, i.e., [1,2,3] represents the series $P_0 + 2P_1 + 3P_2$.

Parameters

c1, c2

[array_like] 1-D arrays of Laguerre series coefficients ordered from low to high.

Returns**out**

[ndarray] Array representing the Laguerre series of their sum.

See also:*lagsub, lagmulx, lagmul, lagdiv, lagpow***Notes**

Unlike multiplication, division, etc., the sum of two Laguerre series is a Laguerre series (without having to “reproject” the result onto the basis set) so addition, just like that of “standard” polynomials, is simply “component-wise.”

Examples

```
>>> from numpy.polynomial.laguerre import lagadd
>>> lagadd([1, 2, 3], [1, 2, 3, 4])
array([2., 4., 6., 4.] )
```

polynomial.laguerre.**lagsub**(*c1*, *c2*)

Subtract one Laguerre series from another.

Returns the difference of two Laguerre series *c1* - *c2*. The sequences of coefficients are from lowest order term to highest, i.e., [1,2,3] represents the series $P_0 + 2P_1 + 3P_2$.

Parameters**c1, c2**

[array_like] 1-D arrays of Laguerre series coefficients ordered from low to high.

Returns**out**

[ndarray] Of Laguerre series coefficients representing their difference.

See also:*lagadd, lagmulx, lagmul, lagdiv, lagpow***Notes**

Unlike multiplication, division, etc., the difference of two Laguerre series is a Laguerre series (without having to “reproject” the result onto the basis set) so subtraction, just like that of “standard” polynomials, is simply “component-wise.”

Examples

```
>>> from numpy.polynomial.laguerre import lagsub
>>> lagsub([1, 2, 3, 4], [1, 2, 3])
array([0., 0., 0., 4.] )
```

`polynomial.laguerre.lagmulx(c)`

Multiply a Laguerre series by x .

Multiply the Laguerre series c by x , where x is the independent variable.

Parameters

c
[array_like] 1-D array of Laguerre series coefficients ordered from low to high.

Returns

out
[ndarray] Array representing the result of the multiplication.

See also:

[*lagadd*](#), [*lagsub*](#), [*lagmul*](#), [*lagdiv*](#), [*lagpow*](#)

Notes

The multiplication uses the recursion relationship for Laguerre polynomials in the form

$$xP_i(x) = -(i+1) * P_{i+1}(x) + (2i+1)P_i(x) - iP_{i-1}(x)$$

Examples

```
>>> from numpy.polynomial.laguerre import lagmulx
>>> lagmulx([1, 2, 3])
array([-1., -1., 11., -9.] )
```

`polynomial.laguerre.lagmul(c1, c2)`

Multiply one Laguerre series by another.

Returns the product of two Laguerre series $c1 * c2$. The arguments are sequences of coefficients, from lowest order “term” to highest, e.g., [1,2,3] represents the series $P_0 + 2*P_1 + 3*P_2$.

Parameters

c1, c2
[array_like] 1-D arrays of Laguerre series coefficients ordered from low to high.

Returns

out
[ndarray] Of Laguerre series coefficients representing their product.

See also:

[*lagadd*](#), [*lagsub*](#), [*lagmulx*](#), [*lagdiv*](#), [*lagpow*](#)

Notes

In general, the (polynomial) product of two C-series results in terms that are not in the Laguerre polynomial basis set. Thus, to express the product as a Laguerre series, it is necessary to “reproject” the product onto said basis set, which may produce “unintuitive” (but correct) results; see Examples section below.

Examples

```
>>> from numpy.polynomial.laguerre import lagmul
>>> lagmul([1, 2, 3], [0, 1, 2])
array([ 8., -13., 38., -51., 36.])
```

`polynomial.laguerre.lagdiv(c1, c2)`

Divide one Laguerre series by another.

Returns the quotient-with-remainder of two Laguerre series $c1 / c2$. The arguments are sequences of coefficients from lowest order “term” to highest, e.g., [1,2,3] represents the series $P_0 + 2P_1 + 3P_2$.

Parameters

c1, c2

[array_like] 1-D arrays of Laguerre series coefficients ordered from low to high.

Returns

[quo, rem]

[ndarrays] Of Laguerre series coefficients representing the quotient and remainder.

See also:

lagadd, lagsub, lagmulx, lagmul, lagpow

Notes

In general, the (polynomial) division of one Laguerre series by another results in quotient and remainder terms that are not in the Laguerre polynomial basis set. Thus, to express these results as a Laguerre series, it is necessary to “reproject” the results onto the Laguerre basis set, which may produce “unintuitive” (but correct) results; see Examples section below.

Examples

```
>>> from numpy.polynomial.laguerre import lagdiv
>>> lagdiv([ 8., -13., 38., -51., 36.], [0, 1, 2])
(array([1., 2., 3.]), array([0.]))
>>> lagdiv([ 9., -12., 38., -51., 36.], [0, 1, 2])
(array([1., 2., 3.]), array([1., 1.]))
```

`polynomial.laguerre.lagpow(c, pow, maxpower=16)`

Raise a Laguerre series to a power.

Returns the Laguerre series c raised to the power pow . The argument c is a sequence of coefficients ordered from low to high. i.e., [1,2,3] is the series $P_0 + 2P_1 + 3P_2$.

Parameters

c
[array_like] 1-D array of Laguerre series coefficients ordered from low to high.

pow
[integer] Power to which the series will be raised

maxpower
[integer, optional] Maximum power allowed. This is mainly to limit growth of the series to unmanageable size. Default is 16

Returns

coef
[ndarray] Laguerre series of power.

See also:

[*lagadd*](#), [*lagsub*](#), [*lagmulx*](#), [*lagmul*](#), [*lagdiv*](#)

Examples

```
>>> from numpy.polynomial.laguerre import lagpow
>>> lagpow([1, 2, 3], 2)
array([ 14., -16.,  56., -72.,  54.])
```

`polynomial.laguerre.lagval(x, c, tensor=True)`

Evaluate a Laguerre series at points x .

If c is of length $n + 1$, this function returns the value:

$$p(x) = c_0 * L_0(x) + c_1 * L_1(x) + \dots + c_n * L_n(x)$$

The parameter x is converted to an array only if it is a tuple or a list, otherwise it is treated as a scalar. In either case, either x or its elements must support multiplication and addition both with themselves and with the elements of c .

If c is a 1-D array, then $p(x)$ will have the same shape as x . If c is multidimensional, then the shape of the result depends on the value of *tensor*. If *tensor* is true the shape will be $c.shape[1:] + x.shape$. If *tensor* is false the shape will be $c.shape[1:]$. Note that scalars have shape $()$.

Trailing zeros in the coefficients will be used in the evaluation, so they should be avoided if efficiency is a concern.

Parameters

x
[array_like, compatible object] If x is a list or tuple, it is converted to an ndarray, otherwise it is left unchanged and treated as a scalar. In either case, x or its elements must support addition and multiplication with themselves and with the elements of c .

c
[array_like] Array of coefficients ordered so that the coefficients for terms of degree n are contained in $c[n]$. If c is multidimensional the remaining indices enumerate multiple polynomials. In the two dimensional case the coefficients may be thought of as stored in the columns of c .

tensor
[boolean, optional] If True, the shape of the coefficient array is extended with ones on the right, one for each dimension of x . Scalars have dimension 0 for this action. The result is that every column of coefficients in c is evaluated for every element of x . If False, x is broadcast

over the columns of c for the evaluation. This keyword is useful when c is multidimensional. The default value is True.

Returns

values

[ndarray, algebra_like] The shape of the return value is described above.

See also:

[*lagval1d*](#), [*laggrid2d*](#), [*lagval3d*](#), [*laggrid3d*](#)

Notes

The evaluation uses Clenshaw recursion, aka synthetic division.

Examples

```
>>> from numpy.polynomial.laguerre import lagval
>>> coef = [1, 2, 3]
>>> lagval(1, coef)
-0.5
>>> lagval([[1, 2], [3, 4]], coef)
array([[ -0.5,  -4. ],
       [-4.5,  -2.]])
```

`polynomial.laguerre.lagval1d(x, y, c)`

Evaluate a 2-D Laguerre series at points (x, y).

This function returns the values:

$$p(x, y) = \sum_{i,j} c_{i,j} * L_i(x) * L_j(y)$$

The parameters x and y are converted to arrays only if they are tuples or a lists, otherwise they are treated as a scalars and they must have the same shape after conversion. In either case, either x and y or their elements must support multiplication and addition both with themselves and with the elements of c .

If c is a 1-D array a one is implicitly appended to its shape to make it 2-D. The shape of the result will be $c.shape[2:] + x.shape$.

Parameters

x, y

[array_like, compatible objects] The two dimensional series is evaluated at the points (x, y) , where x and y must have the same shape. If x or y is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and if it isn't an ndarray it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficient of the term of multi-degree i, j is contained in $c[i, j]$. If c has dimension greater than two the remaining indices enumerate multiple sets of coefficients.

Returns

values

[ndarray, compatible object] The values of the two dimensional polynomial at points formed with pairs of corresponding values from x and y .

See also:

lagval, *laggrid2d*, *lagval3d*, *laggrid3d*

Examples

```
>>> from numpy.polynomial.laguerre import lagval2d
>>> c = [[1, 2], [3, 4]]
>>> lagval2d(1, 1, c)
1.0
```

`polynomial.laguerre.lagval3d(x, y, z, c)`

Evaluate a 3-D Laguerre series at points (x, y, z).

This function returns the values:

$$p(x, y, z) = \sum_{i,j,k} c_{i,j,k} * L_i(x) * L_j(y) * L_k(z)$$

The parameters *x*, *y*, and *z* are converted to arrays only if they are tuples or a lists, otherwise they are treated as a scalars and they must have the same shape after conversion. In either case, either *x*, *y*, and *z* or their elements must support multiplication and addition both with themselves and with the elements of *c*.

If *c* has fewer than 3 dimensions, ones are implicitly appended to its shape to make it 3-D. The shape of the result will be *c*.shape[3:] + *x*.shape.

Parameters

x, y, z

[array_like, compatible object] The three dimensional series is evaluated at the points (*x*, *y*, *z*), where *x*, *y*, and *z* must have the same shape. If any of *x*, *y*, or *z* is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and if it isn't an ndarray it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficient of the term of multi-degree *i,j,k* is contained in *c*[*i*, *j*, *k*]. If *c* has dimension greater than 3 the remaining indices enumerate multiple sets of coefficients.

Returns

values

[ndarray, compatible object] The values of the multidimensional polynomial on points formed with triples of corresponding values from *x*, *y*, and *z*.

See also:

lagval, *lagval2d*, *laggrid2d*, *laggrid3d*

Examples

```
>>> from numpy.polynomial.laguerre import lagval3d
>>> c = [[[1, 2], [3, 4]], [[5, 6], [7, 8]]]
>>> lagval3d(1, 1, 2, c)
-1.0
```

`polynomial.laguerre.lagvalnd`(*pts*, *c*)

Evaluate an N-D Laguerre series at points.

This function returns the values:

$$p(pts, c) = \sum_{i_1, i_2, \dots, i_n} c_{i_1, i_2, \dots, i_n} * L_{i_1}(x_1) * L_{i_2}(x_2) \dots L_{i_n}(x_n)$$

where $x_1, x_2, \dots, x_n = pts$. Note that *pts* may also be an (*n*, *m*) array.

The parameters in *pts* are converted to arrays only if they are tuples or lists, otherwise they are treated as scalars and they must have the same shape after conversion. In either case, either the elements of *pts* or their elements must support multiplication and addition both with themselves and with the elements of *c*.

If *c* has fewer than N dimensions, ones are implicitly appended to its shape to make it N-D. The shape of the result will be *c*.shape[N:] + *pts*[0].shape.

Parameters

pts

[tuple or list of array_like, compatible objects] The N-dimensional series is evaluated at the points (*x*₁, *x*₂, ..., *x*_n) provided in the *pts* iterable, where all elements must have the same shape. If any element is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and if it isn't an ndarray it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficient of the term of multi-degree *i*, *j*, *k*, ... is contained in *c*[*i*, *j*, *k*, ...]. If *c* has dimension greater than N, the remaining indices enumerate multiple sets of coefficients.

Returns

values

[ndarray, compatible object] The values of the multidimensional polynomial on points formed with N-tuples of corresponding values from *pts*.

See also:

[*lagval*](#), [*lagval2d*](#), [*lagval3d*](#)

`polynomial.laguerre.laggrid2d`(*x*, *y*, *c*)

Evaluate a 2-D Laguerre series on the Cartesian product of *x* and *y*.

This function returns the values:

$$p(a, b) = \sum_{i,j} c_{i,j} * L_i(a) * L_j(b)$$

where the points (*a*, *b*) consist of all pairs formed by taking *a* from *x* and *b* from *y*. The resulting points form a grid with *x* in the first dimension and *y* in the second.

The parameters *x* and *y* are converted to arrays only if they are tuples or a lists, otherwise they are treated as scalars. In either case, either *x* and *y* or their elements must support multiplication and addition both with themselves and with the elements of *c*.

If c has fewer than two dimensions, ones are implicitly appended to its shape to make it 2-D. The shape of the result will be $c.shape[2:] + x.shape + y.shape$.

Parameters

x, y

[array_like, compatible objects] The two dimensional series is evaluated at the points in the Cartesian product of x and y . If x or y is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and, if it isn't an ndarray, it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficient of the term of multi-degree i, j is contained in $c[i, j]$. If c has dimension greater than two the remaining indices enumerate multiple sets of coefficients.

Returns

values

[ndarray, compatible object] The values of the two dimensional Chebyshev series at points in the Cartesian product of x and y .

See also:

lagval, lagval2d, lagval3d, laggrid3d

Examples

```
>>> from numpy.polynomial.laguerre import laggrid2d
>>> c = [[1, 2], [3, 4]]
>>> laggrid2d([0, 1], [0, 1], c)
array([[10.,  4.],
       [ 3.,  1.]])
```

`polynomial.laguerre.laggrid3d(x, y, z, c)`

Evaluate a 3-D Laguerre series on the Cartesian product of x , y , and z .

This function returns the values:

$$p(a, b, c) = \sum_{i,j,k} c_{i,j,k} * L_i(a) * L_j(b) * L_k(c)$$

where the points (a, b, c) consist of all triples formed by taking a from x , b from y , and c from z . The resulting points form a grid with x in the first dimension, y in the second, and z in the third.

The parameters x , y , and z are converted to arrays only if they are tuples or a lists, otherwise they are treated as a scalars. In either case, either x , y , and z or their elements must support multiplication and addition both with themselves and with the elements of c .

If c has fewer than three dimensions, ones are implicitly appended to its shape to make it 3-D. The shape of the result will be $c.shape[3:] + x.shape + y.shape + z.shape$.

Parameters

x, y, z

[array_like, compatible objects] The three dimensional series is evaluated at the points in the Cartesian product of x , y , and z . If x , y , or z is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and, if it isn't an ndarray, it is treated as a scalar.

c
[array_like] Array of coefficients ordered so that the coefficients for terms of degree i,j are contained in $c[i,j]$. If c has dimension greater than two the remaining indices enumerate multiple sets of coefficients.

Returns

values
[ndarray, compatible object] The values of the two dimensional polynomial at points in the Cartesian product of x and y .

See also:

lagval, lagval2d, laggrid2d, lagval3d

Examples

```
>>> from numpy.polynomial.laguerre import laggrid3d
>>> c = [[[1, 2], [3, 4]], [[5, 6], [7, 8]]]
>>> laggrid3d([0, 1], [0, 1], [2, 4], c)
array([[[ -4., -44.],
        [ -2., -18.]],
       [[ -2., -14.],
        [ -1., -5.]])
```

Calculus

<i>lagder</i> (c[, m, scl, axis])	Differentiate a Laguerre series.
<i>lagint</i> (c[, m, k, lbnd, scl, axis])	Integrate a Laguerre series.

`polynomial.laguerre.lagder` (*c*, *m*=1, *scl*=1, *axis*=0)

Differentiate a Laguerre series.

Returns the Laguerre series coefficients *c* differentiated *m* times along *axis*. At each iteration the result is multiplied by *scl* (the scaling factor is for use in a linear change of variable). The argument *c* is an array of coefficients from low to high degree along each axis, e.g., [1,2,3] represents the series $1*L_0 + 2*L_1 + 3*L_2$ while [[1,2],[1,2]] represents $1*L_0(x)*L_0(y) + 1*L_1(x)*L_0(y) + 2*L_0(x)*L_1(y) + 2*L_1(x)*L_1(y)$ if *axis*=0 is *x* and *axis*=1 is *y*.

Parameters

c
[array_like] Array of Laguerre series coefficients. If *c* is multidimensional the different axis correspond to different variables with the degree in each axis given by the corresponding index.

m
[int, optional] Number of derivatives taken, must be non-negative. (Default: 1)

scl
[scalar, optional] Each differentiation is multiplied by *scl*. The end result is multiplication by *scl***m*. This is for use in a linear change of variable. (Default: 1)

axis
[int, optional] Axis over which the derivative is taken. (Default: 0).

Returns**der**

[ndarray] Laguerre series of the derivative.

See also:*lagint***Notes**

In general, the result of differentiating a Laguerre series does not resemble the same operation on a power series. Thus the result of this function may be “unintuitive,” albeit correct; see Examples section below.

Examples

```
>>> from numpy.polynomial.laguerre import lagder
>>> lagder([ 1., 1., 1., -3.])
array([1., 2., 3.])
>>> lagder([ 1., 0., 0., -4., 3.], m=2)
array([1., 2., 3.])
```

`polynomial.laguerre.lagint` (*c*, *m*=1, *k*=[], *lbnd*=0, *scl*=1, *axis*=0)

Integrate a Laguerre series.

Returns the Laguerre series coefficients *c* integrated *m* times from *lbnd* along *axis*. At each iteration the resulting series is **multiplied** by *scl* and an integration constant, *k*, is added. The scaling factor is for use in a linear change of variable. (“Buyer beware”: note that, depending on what one is doing, one may want *scl* to be the reciprocal of what one might expect; for more information, see the Notes section below.) The argument *c* is an array of coefficients from low to high degree along each axis, e.g., [1,2,3] represents the series $L_0 + 2*L_1 + 3*L_2$ while [[1,2],[1,2]] represents $1*L_0(x)*L_0(y) + 1*L_1(x)*L_0(y) + 2*L_0(x)*L_1(y) + 2*L_1(x)*L_1(y)$ if *axis*=0 is *x* and *axis*=1 is *y*.

Parameters**c**[array_like] Array of Laguerre series coefficients. If *c* is multidimensional the different axis correspond to different variables with the degree in each axis given by the corresponding index.**m**

[int, optional] Order of integration, must be positive. (Default: 1)

k[[], list, scalar], optional] Integration constant(s). The value of the first integral at *lbnd* is the first value in the list, the value of the second integral at *lbnd* is the second value, etc. If *k* == [] (the default), all constants are set to zero. If *m* == 1, a single scalar can be given instead of a list.**lbnd**

[scalar, optional] The lower bound of the integral. (Default: 0)

scl[scalar, optional] Following each integration the result is *multiplied* by *scl* before the integration constant is added. (Default: 1)**axis**

[int, optional] Axis over which the integral is taken. (Default: 0).

Returns**S**

[ndarray] Laguerre series coefficients of the integral.

Raises**ValueError**If $m < 0$, $\text{len}(k) > m$, $\text{np.ndim}(\text{lbnd}) \neq 0$, or $\text{np.ndim}(scl) \neq 0$.**See also:**[*lagder*](#)**Notes**

Note that the result of each integration is *multiplied* by *scl*. Why is this important to note? Say one is making a linear change of variable $u = ax + b$ in an integral relative to x . Then $dx = du/a$, so one will need to set *scl* equal to $1/a$ - perhaps not what one would have first thought.

Also note that, in general, the result of integrating a C-series needs to be “reprojected” onto the C-series basis set. Thus, typically, the result of this function is “unintuitive,” albeit correct; see Examples section below.

Examples

```
>>> from numpy.polynomial.laguerre import lagint
>>> lagint([1,2,3])
array([ 1.,  1.,  1., -3.])
>>> lagint([1,2,3], m=2)
array([ 1.,  0.,  0., -4.,  3.])
>>> lagint([1,2,3], k=1)
array([ 2.,  1.,  1., -3.])
>>> lagint([1,2,3], lbnd=-1)
array([11.5,  1.,  1., -3. ])
>>> lagint([1,2], m=2, k=[1,2], lbnd=-1)
array([ 11.16666667, -5.,          -3.,          2.,          ])
```

Misc Functions

<i>lagfromroots</i>(roots)	Generate a Laguerre series with given roots.
<i>lagroots</i>(c)	Compute the roots of a Laguerre series.
<i>lagvander</i>(x, deg)	Pseudo-Vandermonde matrix of given degree.
<i>lagvander2d</i>(x, y, deg)	Pseudo-Vandermonde matrix of given degrees.
<i>lagvander3d</i>(x, y, z, deg)	Pseudo-Vandermonde matrix of given degrees.
<i>laggauss</i>(deg)	Gauss-Laguerre quadrature.
<i>lagweight</i>(x)	Weight function of the Laguerre polynomials.
<i>lagcompanion</i>(c)	Return the companion matrix of c.
<i>lagfit</i>(x, y, deg[, rcond, full, w])	Least squares fit of Laguerre series to data.
<i>lagtrim</i>(c[, tol])	Remove "small" "trailing" coefficients from a polynomial.
<i>lagline</i>(off, scl)	Laguerre series whose graph is a straight line.
<i>lag2poly</i>(c)	Convert a Laguerre series to a polynomial.
<i>poly2lag</i>(pol)	Convert a polynomial to a Laguerre series.

`polynomial.laguerre.lagfromroots` (*roots*)

Generate a Laguerre series with given roots.

The function returns the coefficients of the polynomial

$$p(x) = (x - r_0) * (x - r_1) * \dots * (x - r_n),$$

in Laguerre form, where the r_n are the roots specified in *roots*. If a zero has multiplicity n , then it must appear in *roots* n times. For instance, if 2 is a root of multiplicity three and 3 is a root of multiplicity 2, then *roots* looks something like [2, 2, 2, 3, 3]. The roots can appear in any order.

If the returned coefficients are c , then

$$p(x) = c_0 + c_1 * L_1(x) + \dots + c_n * L_n(x)$$

The coefficient of the last term is not generally 1 for monic polynomials in Laguerre form.

Parameters

roots

[array_like] Sequence containing the roots.

Returns

out

[ndarray] 1-D array of coefficients. If all roots are real then *out* is a real array, if some of the roots are complex, then *out* is complex even if all the coefficients in the result are real (see Examples below).

See also:

`numpy.polynomial.polynomial.polyfromroots`
`numpy.polynomial.legendre.legfromroots`
`numpy.polynomial.chebyshev.chebfromroots`
`numpy.polynomial.hermite.hermfromroots`
`numpy.polynomial.hermite_e.hermefromroots`

Examples

```
>>> from numpy.polynomial.laguerre import lagfromroots, lagval
>>> coef = lagfromroots((-1, 0, 1))
>>> lagval((-1, 0, 1), coef)
array([0., 0., 0.])
>>> coef = lagfromroots((-1j, 1j))
>>> lagval((-1j, 1j), coef)
array([0.+0.j, 0.+0.j])
```

`polynomial.laguerre.lagroots` (c)

Compute the roots of a Laguerre series.

Return the roots (a.k.a. “zeros”) of the polynomial

$$p(x) = \sum_i c[i] * L_i(x).$$

Parameters

c

[1-D array_like] 1-D array of coefficients.

Returns**out**

[ndarray] Array of the roots of the series. If all the roots are real, then *out* is also real, otherwise it is complex.

See also:

`numpy.polynomial.polynomial.polyroots`
`numpy.polynomial.legendre.legroots`
`numpy.polynomial.chebyshev.chebroots`
`numpy.polynomial.hermite.hermroots`
`numpy.polynomial.hermite_e.hermroots`

Notes

The root estimates are obtained as the eigenvalues of the companion matrix, Roots far from the origin of the complex plane may have large errors due to the numerical instability of the series for such values. Roots with multiplicity greater than 1 will also show larger errors as the value of the series near such points is relatively insensitive to errors in the roots. Isolated roots near the origin can be improved by a few iterations of Newton's method.

The Laguerre series basis polynomials aren't powers of x so the results of this function may seem unintuitive.

Examples

```
>>> from numpy.polynomial.laguerre import lagroots, lagfromroots
>>> coef = lagfromroots([0, 1, 2])
>>> coef
array([ 2., -8., 12., -6.])
>>> lagroots(coef)
array([-4.4408921e-16,  1.0000000e+00,  2.0000000e+00])
```

`polynomial.laguerre.lagvander`(x , deg)

Pseudo-Vandermonde matrix of given degree.

Returns the pseudo-Vandermonde matrix of degree deg and sample points x . The pseudo-Vandermonde matrix is defined by

$$V[... , i] = L_i(x)$$

where $0 \leq i \leq deg$. The leading indices of V index the elements of x and the last index is the degree of the Laguerre polynomial.

If c is a 1-D array of coefficients of length $n + 1$ and V is the array $V = \text{lagvander}(x, n)$, then $\text{np.dot}(V, c)$ and $\text{lagval}(x, c)$ are the same up to roundoff. This equivalence is useful both for least squares fitting and for the evaluation of a large number of Laguerre series of the same degree and sample points.

Parameters**x**

[array_like] Array of points. The dtype is converted to float64 or complex128 depending on whether any of the elements are complex. If x is scalar it is converted to a 1-D array.

deg

[int] Degree of the resulting matrix.

Returns**vander**

[ndarray] The pseudo-Vandermonde matrix. The shape of the returned matrix is `x.shape + (deg + 1,)`, where The last index is the degree of the corresponding Laguerre polynomial. The dtype will be the same as the converted `x`.

Examples

```
>>> import numpy as np
>>> from numpy.polynomial.laguerre import lagvander
>>> x = np.array([0, 1, 2])
>>> lagvander(x, 3)
array([[ 1.,  1.,  1.,  1.],
       [ 1.,  0., -0.5, -0.66666667],
       [ 1., -1., -1., -0.33333333]])
```

`polynomial.laguerre.lagvander2d(x, y, deg)`

Pseudo-Vandermonde matrix of given degrees.

Returns the pseudo-Vandermonde matrix of degrees `deg` and sample points `(x, y)`. The pseudo-Vandermonde matrix is defined by

$$V[...,(deg[1] + 1) * i + j] = L_i(x) * L_j(y),$$

where $0 \leq i \leq deg[0]$ and $0 \leq j \leq deg[1]$. The leading indices of `V` index the points `(x, y)` and the last index encodes the degrees of the Laguerre polynomials.

If `V = lagvander2d(x, y, [xdeg, ydeg])`, then the columns of `V` correspond to the elements of a 2-D coefficient array `c` of shape `(xdeg + 1, ydeg + 1)` in the order

$$c_{00}, c_{01}, c_{02}, \dots, c_{10}, c_{11}, c_{12}, \dots$$

and `np.dot(V, c.flat)` and `lagval2d(x, y, c)` will be the same up to roundoff. This equivalence is useful both for least squares fitting and for the evaluation of a large number of 2-D Laguerre series of the same degrees and sample points.

Parameters**x, y**

[array_like] Arrays of point coordinates, all of the same shape. The dtypes will be converted to either float64 or complex128 depending on whether any of the elements are complex. Scalars are converted to 1-D arrays.

deg

[list of ints] List of maximum degrees of the form `[x_deg, y_deg]`.

Returns**vander2d**

[ndarray] The shape of the returned matrix is `x.shape + (order,)`, where `order = (deg[0] + 1) * (deg[1] + 1)`. The dtype will be the same as the converted `x` and `y`.

See also:

[`lagvander`](#), [`lagvander3d`](#), [`lagval2d`](#), [`lagval3d`](#)

Examples

```
>>> import numpy as np
>>> from numpy.polynomial.laguerre import lagvander2d
>>> x = np.array([0])
>>> y = np.array([2])
>>> lagvander2d(x, y, [2, 1])
array([[ 1., -1.,  1., -1.,  1., -1.]])
```

`polynomial.laguerre.lagvander3d(x, y, z, deg)`

Pseudo-Vandermonde matrix of given degrees.

Returns the pseudo-Vandermonde matrix of degrees *deg* and sample points (x, y, z) . If *l, m, n* are the given degrees in *x, y, z*, then The pseudo-Vandermonde matrix is defined by

$$V[...,(m+1)(n+1)i + (n+1)j + k] = L_i(x) * L_j(y) * L_k(z),$$

where $0 \leq i \leq l, 0 \leq j \leq m$, and $0 \leq k \leq n$. The leading indices of *V* index the points (x, y, z) and the last index encodes the degrees of the Laguerre polynomials.

If *V* = `lagvander3d(x, y, z, [xdeg, ydeg, zdeg])`, then the columns of *V* correspond to the elements of a 3-D coefficient array *c* of shape $(xdeg + 1, ydeg + 1, zdeg + 1)$ in the order

$$c_{000}, c_{001}, c_{002}, \dots, c_{010}, c_{011}, c_{012}, \dots$$

and `np.dot(V, c.flat)` and `lagval3d(x, y, z, c)` will be the same up to roundoff. This equivalence is useful both for least squares fitting and for the evaluation of a large number of 3-D Laguerre series of the same degrees and sample points.

Parameters

x, y, z

[array_like] Arrays of point coordinates, all of the same shape. The dtypes will be converted to either float64 or complex128 depending on whether any of the elements are complex. Scalars are converted to 1-D arrays.

deg

[list of ints] List of maximum degrees of the form $[x_deg, y_deg, z_deg]$.

Returns

vander3d

[ndarray] The shape of the returned matrix is `x.shape + (order,)`, where `order = (deg[0] + 1) * (deg[1] + 1) * (deg[2] + 1)`. The dtype will be the same as the converted *x, y*, and *z*.

See also:

[*lagvander*](#), [*lagvander3d*](#), [*lagval2d*](#), [*lagval3d*](#)

Examples

```
>>> import numpy as np
>>> from numpy.polynomial.laguerre import lagvander3d
>>> x = np.array([0])
>>> y = np.array([2])
>>> z = np.array([0])
>>> lagvander3d(x, y, z, [2, 1, 3])
array([[ 1.,  1.,  1.,  1., -1., -1., -1., -1.,  1.,  1.,  1.,  1., -1.,
        -1., -1., -1.,  1.,  1.,  1.,  1., -1., -1., -1., -1.]])
```

`polynomial.laguerre.laggauss` (*deg*)

Gauss-Laguerre quadrature.

Computes the sample points and weights for Gauss-Laguerre quadrature. These sample points and weights will correctly integrate polynomials of degree $2 * deg - 1$ or less over the interval $[0, \infty]$ with the weight function $f(x) = \exp(-x)$.

Parameters

deg

[int] Number of sample points and weights. It must be ≥ 1 .

Returns

x

[ndarray] 1-D ndarray containing the sample points.

y

[ndarray] 1-D ndarray containing the weights.

Notes

The results have only been tested up to degree 100 higher degrees may be problematic. The weights are determined by using the fact that

$$w_k = c / (L'_n(x_k) * L_{n-1}(x_k))$$

where c is a constant independent of k and x_k is the k 'th root of L_n , and then scaling the results to get the right value when integrating 1.

Examples

```
>>> from numpy.polynomial.laguerre import laggauss
>>> laggauss(2)
(array([0.58578644, 3.41421356]), array([0.85355339, 0.14644661]))
```

`polynomial.laguerre.lagweight` (*x*)

Weight function of the Laguerre polynomials.

The weight function is $\exp(-x)$ and the interval of integration is $[0, \infty]$. The Laguerre polynomials are orthogonal, but not normalized, with respect to this weight function.

Parameters

x

[array_like] Values at which the weight function will be computed.

Returns**w**[ndarray] The weight function at x .**Examples**

```
>>> from numpy.polynomial.laguerre import lagweight
>>> x = np.array([0, 1, 2])
>>> lagweight(x)
array([1.          , 0.36787944, 0.13533528])
```

`polynomial.laguerre.lagcompanion(c)`

Return the companion matrix of c .

The usual companion matrix of the Laguerre polynomials is already symmetric when c is a basis Laguerre polynomial, so no scaling is applied.

Parameters**c**

[array_like] 1-D array of Laguerre series coefficients ordered from low to high degree.

Returns**mat**

[ndarray] Companion matrix of dimensions (deg, deg).

Examples

```
>>> from numpy.polynomial.laguerre import lagcompanion
>>> lagcompanion([1, 2, 3])
array([[ 1.          , -0.33333333],
       [-1.          ,  4.33333333]])
```

`polynomial.laguerre.lagfit(x, y, deg, rcond=None, full=False, w=None)`

Least squares fit of Laguerre series to data.

Return the coefficients of a Laguerre series of degree deg that is the least squares fit to the data values y given at points x . If y is 1-D the returned coefficients will also be 1-D. If y is 2-D multiple fits are done, one for each column of y , and the resulting coefficients are stored in the corresponding columns of a 2-D return. The fitted polynomial(s) are in the form

$$p(x) = c_0 + c_1 * L_1(x) + \dots + c_n * L_n(x),$$

where n is deg .

Parameters**x**[array_like, shape (M,)] x-coordinates of the M sample points ($x[i]$, $y[i]$).**y**

[array_like, shape (M,) or (M, K)] y-coordinates of the sample points. Several data sets of sample points sharing the same x-coordinates can be fitted at once by passing in a 2D-array that contains one dataset per column.

deg

[int or 1-D array_like] Degree(s) of the fitting polynomials. If *deg* is a single integer all terms up to and including the *deg*'th term are included in the fit. For NumPy versions $\geq 1.11.0$ a list of integers specifying the degrees of the terms to include may be used instead.

rcond

[float, optional] Relative condition number of the fit. Singular values smaller than this relative to the largest singular value will be ignored. The default value is $\text{len}(x) \cdot \text{eps}$, where *eps* is the relative precision of the float type, about $2e-16$ in most cases.

full

[bool, optional] Switch determining nature of return value. When it is False (the default) just the coefficients are returned, when True diagnostic information from the singular value decomposition is also returned.

w

[array_like, shape (M,), optional] Weights. If not None, the weight $w[i]$ applies to the unsquared residual $y[i] - \hat{y}[i]$ at $x[i]$. Ideally the weights are chosen so that the errors of the products $w[i] \cdot y[i]$ all have the same variance. When using inverse-variance weighting, use $w[i] = 1/\text{sigma}(y[i])$. The default value is None.

Returns**coef**

[ndarray, shape (M,) or (M, K)] Laguerre coefficients ordered from low to high. If *y* was 2-D, the coefficients for the data in column *k* of *y* are in column *k*.

[residuals, rank, singular_values, rcond]

[list] These values are only returned if `full == True`

- residuals – sum of squared residuals of the least squares fit
- rank – the numerical rank of the scaled Vandermonde matrix
- singular_values – singular values of the scaled Vandermonde matrix
- rcond – value of *rcond*.

For more details, see [`numpy.linalg.lstsq`](#).

Warns**RankWarning**

The rank of the coefficient matrix in the least-squares fit is deficient. The warning is only raised if `full == False`. The warnings can be turned off by

```
>>> import warnings
>>> warnings.simplefilter('ignore', np.exceptions.RankWarning)
```

See also:

```
numpy.polynomial.polynomial.polyfit
numpy.polynomial.legendre.legfit
numpy.polynomial.chebyshev.chebfit
numpy.polynomial.hermite.hermfit
numpy.polynomial.hermite\_e.hermefit
lagval
```

Evaluates a Laguerre series.

```
lagvander
```

pseudo Vandermonde matrix of Laguerre series.

lagweight

Laguerre weight function.

numpy.linalg.lstsq

Computes a least-squares fit from the matrix.

scipy.interpolate.UnivariateSpline

Computes spline fits.

Notes

The solution is the coefficients of the Laguerre series p that minimizes the sum of the weighted squared errors

$$E = \sum_j w_j^2 * |y_j - p(x_j)|^2,$$

where the w_j are the weights. This problem is solved by setting up as the (typically) overdetermined matrix equation

$$V(x) * c = w * y,$$

where V is the weighted pseudo Vandermonde matrix of x , c are the coefficients to be solved for, w are the weights, and y are the observed values. This equation is then solved using the singular value decomposition of V .

If some of the singular values of V are so small that they are neglected, then a [RankWarning](#) will be issued. This means that the coefficient values may be poorly determined. Using a lower order fit will usually get rid of the warning. The `rcond` parameter can also be set to a value smaller than its default, but the resulting fit may be spurious and have large contributions from roundoff error.

Fits using Laguerre series are probably most useful when the data can be approximated by $\sqrt{w(x)} * p(x)$, where $w(x)$ is the Laguerre weight. In that case the weight $\sqrt{w(x[i])}$ should be used together with data values $y[i] / \sqrt{w(x[i])}$. The weight function is available as [lagweight](#).

References

[1]

Examples

```
>>> import numpy as np
>>> from numpy.polynomial.laguerre import lagfit, lagval
>>> x = np.linspace(0, 10)
>>> rng = np.random.default_rng()
>>> err = rng.normal(scale=1./10, size=len(x))
>>> y = lagval(x, [1, 2, 3]) + err
>>> lagfit(x, y, 2)
array([1.00578369, 1.99417356, 2.99827656]) # may vary
```

`polynomial.laguerre.lagtrim(c, tol=0)`

Remove “small” “trailing” coefficients from a polynomial.

“Small” means “small in absolute value” and is controlled by the parameter `tol`; “trailing” means highest order coefficient(s), e.g., in `[0, 1, 1, 0, 0]` (which represents $0 + x + x^2 + 0x^3 + 0x^4$) both the 3-rd and 4-th order coefficients would be “trimmed.”

Parameters

c
[array_like] 1-d array of coefficients, ordered from lowest order to highest.

tol
[number, optional] Trailing (i.e., highest order) elements with absolute value less than or equal to *tol* (default value is zero) are removed.

Returns

trimmed
[ndarray] 1-d array with trailing zeros removed. If the resulting series would be empty, a series containing a single zero is returned.

Raises

ValueError
If *tol* < 0

Examples

```
>>> from numpy.polynomial import polyutils as pu
>>> pu.trimcoef((0,0,3,0,5,0,0))
array([0., 0., 3., 0., 5.])
>>> pu.trimcoef((0,0,1e-3,0,1e-5,0,0),1e-3) # item == tol is trimmed
array([0.])
>>> i = complex(0,1) # works for complex
>>> pu.trimcoef((3e-4,1e-3*(1-i),5e-4,2e-5*(1+i)), 1e-3)
array([0.0003+0.j, 0.001 -0.001j])
```

`polynomial.laguerre.lagline` (*off*, *scl*)

Laguerre series whose graph is a straight line.

Parameters

off, scl
[scalars] The specified line is given by *off* + *scl***x*.

Returns

y
[ndarray] This module's representation of the Laguerre series for *off* + *scl***x*.

See also:

`numpy.polynomial.polynomial.polyline`
`numpy.polynomial.chebyshev.chebline`
`numpy.polynomial.legendre.legline`
`numpy.polynomial.hermite.hermline`
`numpy.polynomial.hermite_e.hermeline`

Examples

```
>>> from numpy.polynomial.laguerre import lagline, lagval
>>> lagval(0, lagline(3, 2))
3.0
>>> lagval(1, lagline(3, 2))
5.0
```

`polynomial.laguerre.lag2poly(c)`

Convert a Laguerre series to a polynomial.

Convert an array representing the coefficients of a Laguerre series, ordered from lowest degree to highest, to an array of the coefficients of the equivalent polynomial (relative to the “standard” basis) ordered from lowest to highest degree.

Parameters

c
[array_like] 1-D array containing the Laguerre series coefficients, ordered from lowest order term to highest.

Returns

pol
[ndarray] 1-D array containing the coefficients of the equivalent polynomial (relative to the “standard” basis) ordered from lowest order term to highest.

See also:

[*poly2lag*](#)

Notes

The easy way to do conversions between polynomial basis sets is to use the convert method of a class instance.

Examples

```
>>> from numpy.polynomial.laguerre import lag2poly
>>> lag2poly([ 23., -63., 58., -18.])
array([0., 1., 2., 3.]
```

`polynomial.laguerre.poly2lag(pol)`

Convert a polynomial to a Laguerre series.

Convert an array representing the coefficients of a polynomial (relative to the “standard” basis) ordered from lowest degree to highest, to an array of the coefficients of the equivalent Laguerre series, ordered from lowest to highest degree.

Parameters

pol
[array_like] 1-D array containing the polynomial coefficients

Returns

c
[ndarray] 1-D array containing the coefficients of the equivalent Laguerre series.

See also:

lag2poly

Notes

The easy way to do conversions between polynomial basis sets is to use the `convert` method of a class instance.

Examples

```
>>> import numpy as np
>>> from numpy.polynomial.laguerre import poly2lag
>>> poly2lag(np.arange(4))
array([ 23., -63.,  58., -18.]
```

See also

numpy.polynomial

Legendre Series (`numpy.polynomial.legendre`)

This module provides a number of objects (mostly functions) useful for dealing with Legendre series, including a *Legendre* class that encapsulates the usual arithmetic operations. (General information on how this module represents and works with such polynomials is in the docstring for its “parent” sub-package, *numpy.polynomial*).

Classes

<i>Legendre</i> (coef[, domain, window, symbol])	A Legendre series class.
--	--------------------------

class `numpy.polynomial.legendre.Legendre` (coef, domain=None, window=None, symbol='x')

A Legendre series class.

The Legendre class provides the standard Python numerical methods ‘+’, ‘-’, ‘*’, ‘/’, ‘%’, ‘divmod’, ‘**’, and ‘()’ as well as the attributes and methods listed below.

Parameters

coef

[array_like] Legendre coefficients in order of increasing degree, i.e., (1, 2, 3) gives $1 * P_0(x) + 2 * P_1(x) + 3 * P_2(x)$.

domain

[(2,) array_like, optional] Domain to use. The interval [domain[0], domain[1]] is mapped to the interval [window[0], window[1]] by shifting and scaling. The default value is [-1., 1.].

window

[(2,) array_like, optional] Window, see domain for its use. The default value is [-1., 1.].

symbol

[str, optional] Symbol used to represent the independent variable in string representations of the polynomial expression, e.g. for printing. The symbol must be a valid Python identifier. Default value is 'x'.

New in version 1.24.

Attributes**symbol****Methods**

<code>__call__(arg)</code>	Call self as a function.
<code>basis(deg[, domain, window, symbol])</code>	Series basis polynomial of degree <i>deg</i> .
<code>cast(series[, domain, window])</code>	Convert series to series of this class.
<code>convert([domain, kind, window])</code>	Convert series to a different kind and/or domain and/or window.
<code>copy()</code>	Return a copy.
<code>cutdeg(deg)</code>	Truncate series to the given degree.
<code>degree()</code>	The degree of the series.
<code>deriv([m])</code>	Differentiate.
<code>fit(x, y, deg[, domain, rcond, full, w, ...])</code>	Least squares fit to data.
<code>fromroots(roots[, domain, window, symbol])</code>	Return series instance that has the specified roots.
<code>has_samecoef(other)</code>	Check if coefficients match.
<code>has_samedomain(other)</code>	Check if domains match.
<code>has_sametype(other)</code>	Check if types match.
<code>has_samewindow(other)</code>	Check if windows match.
<code>identity([domain, window, symbol])</code>	Identity function.
<code>integ([m, k, lbnd])</code>	Integrate.
<code>linspace([n, domain])</code>	Return x, y values at equally spaced points in domain.
<code>mapparms()</code>	Return the mapping parameters.
<code>roots()</code>	Return the roots of the series polynomial.
<code>trim([tol])</code>	Remove trailing coefficients
<code>truncate(size)</code>	Truncate series to length <i>size</i> .

method

`polynomial.legendre.Legendre.__call__(arg)`

Call self as a function.

method

classmethod `polynomial.legendre.Legendre.basis(deg, domain=None, window=None, symbol='x')`

Series basis polynomial of degree *deg*.

Returns the series representing the basis polynomial of degree *deg*.

Parameters**deg**

[int] Degree of the basis polynomial for the series. Must be ≥ 0 .

domain

[[None, array_like], optional] If given, the array must be of the form `[beg, end]`, where

`beg` and `end` are the endpoints of the domain. If `None` is given then the class domain is used. The default is `None`.

window

[`None`, `array_like`], optional] If given, the resulting array must be of the form [`beg`, `end`], where `beg` and `end` are the endpoints of the window. If `None` is given then the class window is used. The default is `None`.

symbol

[`str`, optional] Symbol representing the independent variable. Default is `'x'`.

Returns**new_series**

[`series`] A series with the coefficient of the *deg* term set to one and all others zero.

method

classmethod `polynomial.legendre.Legendre.cast` (*series*, *domain=None*, *window=None*)

Convert series to series of this class.

The *series* is expected to be an instance of some polynomial series of one of the types supported by the `numpy.polynomial` module, but could be some other class that supports the `convert` method.

Parameters**series**

[`series`] The series instance to be converted.

domain

[`None`, `array_like`], optional] If given, the array must be of the form [`beg`, `end`], where `beg` and `end` are the endpoints of the domain. If `None` is given then the class domain is used. The default is `None`.

window

[`None`, `array_like`], optional] If given, the resulting array must be of the form [`beg`, `end`], where `beg` and `end` are the endpoints of the window. If `None` is given then the class window is used. The default is `None`.

Returns**new_series**

[`series`] A series of the same kind as the calling class and equal to *series* when evaluated.

See also:***convert***

similar instance method

method

`polynomial.legendre.Legendre.convert` (*domain=None*, *kind=None*, *window=None*)

Convert series to a different kind and/or domain and/or window.

Parameters**domain**

[`array_like`, optional] The domain of the converted series. If the value is `None`, the default domain of *kind* is used.

kind

[`class`, optional] The polynomial series type class to which the current instance should be converted. If *kind* is `None`, then the class of the current instance is used.

window

[array_like, optional] The window of the converted series. If the value is None, the default window of *kind* is used.

Returns**new_series**

[series] The returned class can be of different type than the current instance and/or have a different domain and/or different window.

Notes

Conversion between domains and class types can result in numerically ill defined series.

method

```
polynomial.legendre.Legendre.copy()
```

Return a copy.

Returns**new_series**

[series] Copy of self.

method

```
polynomial.legendre.Legendre.cutdeg(deg)
```

Truncate series to the given degree.

Reduce the degree of the series to *deg* by discarding the high order terms. If *deg* is greater than the current degree a copy of the current series is returned. This can be useful in least squares where the coefficients of the high degree terms may be very small.

Parameters**deg**

[non-negative int] The series is reduced to degree *deg* by discarding the high order terms. The value of *deg* must be a non-negative integer.

Returns**new_series**

[series] New instance of series with reduced degree.

method

```
polynomial.legendre.Legendre.degree()
```

The degree of the series.

Returns**degree**

[int] Degree of the series, one less than the number of coefficients.

Examples

Create a polynomial object for $1 + 7x + 4x^2$:

```
>>> np.polynomial.set_default_printstyle("unicode")
>>> poly = np.polynomial.Polynomial([1, 7, 4])
>>> print(poly)
1.0 + 7.0·x + 4.0·x2
>>> poly.degree()
2
```

Note that this method does not check for non-zero coefficients. You must trim the polynomial to remove any trailing zeroes:

```
>>> poly = np.polynomial.Polynomial([1, 7, 0])
>>> print(poly)
1.0 + 7.0·x + 0.0·x2
>>> poly.degree()
2
>>> poly.trim().degree()
1
```

method

`polynomial.legendre.Legendre.deriv(m=1)`

Differentiate.

Return a series instance of that is the derivative of the current series.

Parameters

m

[non-negative int] Find the derivative of order *m*.

Returns

new_series

[series] A new series representing the derivative. The domain is the same as the domain of the differentiated series.

method

classmethod `polynomial.legendre.Legendre.fit(x, y, deg, domain=None, rcond=None, full=False, w=None, window=None, symbol='x')`

Least squares fit to data.

Return a series instance that is the least squares fit to the data *y* sampled at *x*. The domain of the returned instance can be specified and this will often result in a superior fit with less chance of ill conditioning.

Parameters

x

[array_like, shape (M,)] x-coordinates of the *M* sample points (*x*[*i*], *y*[*i*]).

y

[array_like, shape (M,)] y-coordinates of the *M* sample points (*x*[*i*], *y*[*i*]).

deg

[int or 1-D array_like] Degree(s) of the fitting polynomials. If *deg* is a single integer all terms

up to and including the *deg*'th term are included in the fit. For NumPy versions $\geq 1.11.0$ a list of integers specifying the degrees of the terms to include may be used instead.

domain

[{None, [beg, end], []}, optional] Domain to use for the returned series. If None, then a minimal domain that covers the points x is chosen. If [] the class domain is used. The default value was the class domain in NumPy 1.4 and None in later versions. The [] option was added in numpy 1.5.0.

rcond

[float, optional] Relative condition number of the fit. Singular values smaller than this relative to the largest singular value will be ignored. The default value is $\text{len}(x) * \text{eps}$, where eps is the relative precision of the float type, about $2e-16$ in most cases.

full

[bool, optional] Switch determining nature of return value. When it is False (the default) just the coefficients are returned, when True diagnostic information from the singular value decomposition is also returned.

w

[array_like, shape (M,), optional] Weights. If not None, the weight $w[i]$ applies to the unsquared residual $y[i] - \hat{y}[i]$ at $x[i]$. Ideally the weights are chosen so that the errors of the products $w[i] * y[i]$ all have the same variance. When using inverse-variance weighting, use $w[i] = 1/\text{sigma}(y[i])$. The default value is None.

window

[[[beg, end]], optional] Window to use for the returned series. The default value is the default class domain

symbol

[str, optional] Symbol representing the independent variable. Default is 'x'.

Returns

new_series

[series] A series that represents the least squares fit to the data and has the domain and window specified in the call. If the coefficients for the unscaled and unshifted basis polynomials are of interest, do `new_series.convert().coef`.

[resid, rank, sv, rcond]

[list] These values are only returned if `full == True`

- resid – sum of squared residuals of the least squares fit
- rank – the numerical rank of the scaled Vandermonde matrix
- sv – singular values of the scaled Vandermonde matrix
- rcond – value of *rcond*.

For more details, see `linalg.lstsq`.

method

classmethod `polynomial.legendre.Legendre.fromroots` (*roots*, *domain=[]*, *window=None*, *symbol='x'*)

Return series instance that has the specified roots.

Returns a series representing the product $(x - r[0]) * (x - r[1]) * \dots * (x - r[n-1])$, where r is a list of roots.

Parameters

roots

[array_like] List of roots.

domain

[[], None, array_like], optional] Domain for the resulting series. If None the domain is the interval from the smallest root to the largest. If [] the domain is the class domain. The default is [].

window

[{None, array_like}, optional] Window for the returned series. If None the class window is used. The default is None.

symbol

[str, optional] Symbol representing the independent variable. Default is 'x'.

Returns**new_series**

[series] Series with the specified roots.

method

`polynomial.legendre.Legendre.has_samecoef (other)`

Check if coefficients match.

Parameters**other**

[class instance] The other class must have the `coef` attribute.

Returns**bool**

[boolean] True if the coefficients are the same, False otherwise.

method

`polynomial.legendre.Legendre.has_samedomain (other)`

Check if domains match.

Parameters**other**

[class instance] The other class must have the `domain` attribute.

Returns**bool**

[boolean] True if the domains are the same, False otherwise.

method

`polynomial.legendre.Legendre.has_sametype (other)`

Check if types match.

Parameters**other**

[object] Class instance.

Returns**bool**

[boolean] True if other is same class as self

method

`polynomial.legendre.Legendre.has_samewindow (other)`

Check if windows match.

Parameters

other

[class instance] The other class must have the `window` attribute.

Returns

bool

[boolean] True if the windows are the same, False otherwise.

method

classmethod `polynomial.legendre.Legendre.identity (domain=None, window=None, symbol='x')`

Identity function.

If p is the returned series, then $p(x) == x$ for all values of x .

Parameters

domain

[{None, array_like}, optional] If given, the array must be of the form `[beg, end]`, where `beg` and `end` are the endpoints of the domain. If None is given then the class domain is used. The default is None.

window

[{None, array_like}, optional] If given, the resulting array must be if the form `[beg, end]`, where `beg` and `end` are the endpoints of the window. If None is given then the class window is used. The default is None.

symbol

[str, optional] Symbol representing the independent variable. Default is 'x'.

Returns

new_series

[series] Series of representing the identity.

method

`polynomial.legendre.Legendre.integ (m=1, k=[], lbnd=None)`

Integrate.

Return a series instance that is the definite integral of the current series.

Parameters

m

[non-negative int] The number of integrations to perform.

k

[array_like] Integration constants. The first constant is applied to the first integration, the second to the second, and so on. The list of values must less than or equal to m in length and any missing values are set to zero.

lbnd

[Scalar] The lower bound of the definite integral.

Returns

new_series

[series] A new series representing the integral. The domain is the same as the domain of the integrated series.

method

`polynomial.legendre.Legendre.linspace` (*n=100, domain=None*)

Return x, y values at equally spaced points in domain.

Returns the x, y values at *n* linearly spaced points across the domain. Here y is the value of the polynomial at the points x. By default the domain is the same as that of the series instance. This method is intended mostly as a plotting aid.

Parameters**n**

[int, optional] Number of point pairs to return. The default value is 100.

domain

[[None, array_like], optional] If not None, the specified domain is used instead of that of the calling instance. It should be of the form [beg, end]. The default is None which case the class domain is used.

Returns**x, y**

[ndarray] x is equal to `linspace(self.domain[0], self.domain[1], n)` and y is the series evaluated at element of x.

method

`polynomial.legendre.Legendre.mapparms` ()

Return the mapping parameters.

The returned values define a linear map $\text{off} + \text{scl} * x$ that is applied to the input arguments before the series is evaluated. The map depends on the domain and window; if the current domain is equal to the window the resulting map is the identity. If the coefficients of the series instance are to be used by themselves outside this class, then the linear function must be substituted for the x in the standard representation of the base polynomials.

Returns**off, scl**

[float or complex] The mapping function is defined by $\text{off} + \text{scl} * x$.

Notes

If the current domain is the interval $[l1, r1]$ and the window is $[l2, r2]$, then the linear mapping function L is defined by the equations:

$$\begin{aligned} L(l1) &= l2 \\ L(r1) &= r2 \end{aligned}$$

method

`polynomial.legendre.Legendre.roots` ()

Return the roots of the series polynomial.

Compute the roots for the series. Note that the accuracy of the roots decreases the further outside the domain they lie.

Returns**roots**

[ndarray] Array containing the roots of the series.

method

`polynomial.legendre.Legendre.trim (tol=0)`

Remove trailing coefficients

Remove trailing coefficients until a coefficient is reached whose absolute value greater than *tol* or the beginning of the series is reached. If all the coefficients would be removed the series is set to `[0]`. A new series instance is returned with the new coefficients. The current instance remains unchanged.

Parameters**tol**

[non-negative number.] All trailing coefficients less than *tol* will be removed.

Returns**new_series**

[series] New instance of series with trimmed coefficients.

method

`polynomial.legendre.Legendre.truncate (size)`

Truncate series to length *size*.

Reduce the series to length *size* by discarding the high degree terms. The value of *size* must be a positive integer. This can be useful in least squares where the coefficients of the high degree terms may be very small.

Parameters**size**

[positive int] The series is reduced to length *size* by discarding the high degree terms. The value of *size* must be a positive integer.

Returns**new_series**

[series] New instance of series with truncated coefficients.

Constants

<code>legdomain</code>	<code>ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None)</code>
<code>legzero</code>	<code>ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None)</code>
<code>legone</code>	<code>ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None)</code>
<code>legx</code>	<code>ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None)</code>

`polynomial.legendre.legdomain = array([-1., 1.])`

`ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None) –`

`ndarray(shape, dtype=np.float64, buffer=None, offset=0, strides=None, order=None)`

An array object represents a multidimensional, homogeneous array of fixed-size items. An associated data-type object describes the format of each element in the array (its byte-order, how many bytes it occupies in memory, whether it is an integer, a floating point number, or something else, etc.)

Arrays should be constructed using `array`, `zeros` or `empty` (refer to the See Also section below). The parameters given here refer to a low-level method (`ndarray(...)`) for instantiating an array.

For more information, refer to the `numpy` module and examine the methods and attributes of an array.

Parameters

(for the `__new__` method; see Notes below)

shape

[tuple of ints] Shape of created array.

dtype

[data-type, optional] Any object that can be interpreted as a numpy data type. Default is `numpy.float64`.

buffer

[object exposing buffer interface, optional] Used to fill the array with data.

offset

[int, optional] Offset of array data in buffer.

strides

[tuple of ints, optional] Strides of data in memory.

order

['C', 'F'], optional] Row-major (C-style) or column-major (Fortran-style) order.

Attributes

T

[ndarray] Transpose of the array.

data

[buffer] The array's elements, in memory.

dtype

[dtype object] Describes the format of the elements in the array.

flags

[dict] Dictionary containing information related to memory use, e.g., 'C_CONTIGUOUS', 'OWNDATA', 'WRITEABLE', etc.

flat

[numpy.flatiter object] Flattened version of the array as an iterator. The iterator allows assignments, e.g., `x.flat = 3` (See `ndarray.flat` for assignment examples; TODO).

imag

[ndarray] Imaginary part of the array.

real

[ndarray] Real part of the array.

size

[int] Number of elements in the array.

itemsize

[int] The memory use of each array element in bytes.

nbytes

[int] The total number of bytes required to store the array data, i.e., `itemsize * size`.

ndim

[int] The array's number of dimensions.

shape

[tuple of ints] Shape of the array.

strides

[tuple of ints] The step-size required to move from one element to the next in memory. For example, a contiguous (3, 4) array of type `int16` in C-order has strides (8, 2). This implies that to move from element to element in memory requires jumps of 2 bytes. To move from row-to-row, one needs to jump 8 bytes at a time ($2 * 4$).

ctypes

[ctypes object] Class containing properties of the array needed for interaction with ctypes.

base

[ndarray] If the array is a view into another array, that array is its *base* (unless that array is also a view). The *base* array is where the array data is actually stored.

See also:**`array`**

Construct an array.

`zeros`

Create an array, each element of which is zero.

`empty`

Create an array, but leave its allocated memory unchanged (i.e., it contains “garbage”).

`dtype`

Create a data-type.

`numpy.typing.NDArray`

An ndarray alias *generic* w.r.t. its `dtype.type`.

Notes

There are two modes of creating an array using `__new__`:

1. If *buffer* is None, then only *shape*, *dtype*, and *order* are used.
2. If *buffer* is an object exposing the buffer interface, then all keywords are interpreted.

No `__init__` method is needed because the array is fully initialized after the `__new__` method.

Examples

These examples illustrate the low-level `ndarray` constructor. Refer to the *See Also* section above for easier ways of constructing an ndarray.

First mode, *buffer* is None:

```
>>> import numpy as np
>>> np.ndarray(shape=(2,2), dtype=np.float64, order='F')
array([[0.0e+000, 0.0e+000], # random
       [      nan, 2.5e-323]])
```

Second mode:

```
>>> np.ndarray((2,), buffer=np.array([1,2,3]),
...           offset=np.int_().itemsize,
...           dtype=np.int_) # offset = 1*itemsize, i.e. skip first element
array([2, 3])
```

`polynomial.legendre.legzero = array([0])`

`ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None) -`

`ndarray(shape, dtype=np.float64, buffer=None, offset=0, strides=None, order=None)`

An array object represents a multidimensional, homogeneous array of fixed-size items. An associated data-type object describes the format of each element in the array (its byte-order, how many bytes it occupies in memory, whether it is an integer, a floating point number, or something else, etc.)

Arrays should be constructed using *array*, *zeros* or *empty* (refer to the See Also section below). The parameters given here refer to a low-level method (*ndarray(...)*) for instantiating an array.

For more information, refer to the *numpy* module and examine the methods and attributes of an array.

Parameters

(for the `__new__` method; see Notes below)

shape

[tuple of ints] Shape of created array.

dtype

[data-type, optional] Any object that can be interpreted as a numpy data type. Default is *numpy.float64*.

buffer

[object exposing buffer interface, optional] Used to fill the array with data.

offset

[int, optional] Offset of array data in buffer.

strides

[tuple of ints, optional] Strides of data in memory.

order

[['C', 'F'], optional] Row-major (C-style) or column-major (Fortran-style) order.

Attributes

T

[ndarray] Transpose of the array.

data

[buffer] The array's elements, in memory.

dtype

[dtype object] Describes the format of the elements in the array.

flags

[dict] Dictionary containing information related to memory use, e.g., 'C_CONTIGUOUS', 'OWNDATA', 'WRITEABLE', etc.

flat

[numpy.flatiter object] Flattened version of the array as an iterator. The iterator allows assignments, e.g., `x.flat = 3` (See *ndarray.flat* for assignment examples; TODO).

imag

[ndarray] Imaginary part of the array.

real

[ndarray] Real part of the array.

size

[int] Number of elements in the array.

itemsize

[int] The memory use of each array element in bytes.

nbytes

[int] The total number of bytes required to store the array data, i.e., `itemsize * size`.

ndim

[int] The array's number of dimensions.

shape

[tuple of ints] Shape of the array.

strides

[tuple of ints] The step-size required to move from one element to the next in memory. For example, a contiguous (3, 4) array of type `int16` in C-order has strides (8, 2). This implies that to move from element to element in memory requires jumps of 2 bytes. To move from row-to-row, one needs to jump 8 bytes at a time (2 * 4).

ctypes

[ctypes object] Class containing properties of the array needed for interaction with ctypes.

base

[ndarray] If the array is a view into another array, that array is its *base* (unless that array is also a view). The *base* array is where the array data is actually stored.

See also:***array***

Construct an array.

zeros

Create an array, each element of which is zero.

empty

Create an array, but leave its allocated memory unchanged (i.e., it contains “garbage”).

dtype

Create a data-type.

numpy.typing.NDArray

An ndarray alias *generic* w.r.t. its *dtype.type*.

Notes

There are two modes of creating an array using `__new__`:

1. If *buffer* is None, then only *shape*, *dtype*, and *order* are used.
2. If *buffer* is an object exposing the buffer interface, then all keywords are interpreted.

No `__init__` method is needed because the array is fully initialized after the `__new__` method.

Examples

These examples illustrate the low-level `ndarray` constructor. Refer to the *See Also* section above for easier ways of constructing an ndarray.

First mode, *buffer* is None:

```
>>> import numpy as np
>>> np.ndarray(shape=(2,2), dtype=np.float64, order='F')
array([[0.0e+000, 0.0e+000], # random
       [      nan, 2.5e-323]])
```

Second mode:

```
>>> np.ndarray((2,), buffer=np.array([1,2,3]),
...           offset=np.int_().itemsize,
...           dtype=np.int_) # offset = 1*itemsize, i.e. skip first element
array([2, 3])
```

```
polynomial.legendre.legone = array([1])
```

`ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None) –`

`ndarray(shape, dtype=np.float64, buffer=None, offset=0, strides=None, order=None)`

An array object represents a multidimensional, homogeneous array of fixed-size items. An associated data-type object describes the format of each element in the array (its byte-order, how many bytes it occupies in memory, whether it is an integer, a floating point number, or something else, etc.)

Arrays should be constructed using `array`, `zeros` or `empty` (refer to the *See Also* section below). The parameters given here refer to a low-level method (`ndarray(...)`) for instantiating an array.

For more information, refer to the `numpy` module and examine the methods and attributes of an array.

Parameters

(for the `__new__` method; see Notes below)

shape

[tuple of ints] Shape of created array.

dtype

[data-type, optional] Any object that can be interpreted as a numpy data type. Default is `numpy.float64`.

buffer

[object exposing buffer interface, optional] Used to fill the array with data.

offset

[int, optional] Offset of array data in buffer.

strides

[tuple of ints, optional] Strides of data in memory.

order

[{'C', 'F'}, optional] Row-major (C-style) or column-major (Fortran-style) order.

Attributes

T

[ndarray] Transpose of the array.

data

[buffer] The array's elements, in memory.

dtype

[dtype object] Describes the format of the elements in the array.

flags

[dict] Dictionary containing information related to memory use, e.g., ‘C_CONTIGUOUS’, ‘OWNDATA’, ‘WRITEABLE’, etc.

flat

[numpy.flatiter object] Flattened version of the array as an iterator. The iterator allows assignments, e.g., `x.flat = 3` (See [ndarray.flat](#) for assignment examples; TODO).

imag

[ndarray] Imaginary part of the array.

real

[ndarray] Real part of the array.

size

[int] Number of elements in the array.

itemsize

[int] The memory use of each array element in bytes.

nbytes

[int] The total number of bytes required to store the array data, i.e., `itemsize * size`.

ndim

[int] The array’s number of dimensions.

shape

[tuple of ints] Shape of the array.

strides

[tuple of ints] The step-size required to move from one element to the next in memory. For example, a contiguous (3, 4) array of type `int16` in C-order has strides (8, 2). This implies that to move from element to element in memory requires jumps of 2 bytes. To move from row-to-row, one needs to jump 8 bytes at a time (2 * 4).

ctypes

[ctypes object] Class containing properties of the array needed for interaction with ctypes.

base

[ndarray] If the array is a view into another array, that array is its *base* (unless that array is also a view). The *base* array is where the array data is actually stored.

See also:**[array](#)**

Construct an array.

[zeros](#)

Create an array, each element of which is zero.

[empty](#)

Create an array, but leave its allocated memory unchanged (i.e., it contains “garbage”).

[dtype](#)

Create a data-type.

[numpy.typing.NDArray](#)

An ndarray alias *generic* w.r.t. its [dtype.type](#).

Notes

There are two modes of creating an array using `__new__`:

1. If *buffer* is `None`, then only *shape*, *dtype*, and *order* are used.
2. If *buffer* is an object exposing the buffer interface, then all keywords are interpreted.

No `__init__` method is needed because the array is fully initialized after the `__new__` method.

Examples

These examples illustrate the low-level *ndarray* constructor. Refer to the *See Also* section above for easier ways of constructing an ndarray.

First mode, *buffer* is `None`:

```
>>> import numpy as np
>>> np.ndarray(shape=(2,2), dtype=np.float64, order='F')
array([[0.0e+000, 0.0e+000], # random
       [      nan, 2.5e-323]])
```

Second mode:

```
>>> np.ndarray((2,), buffer=np.array([1,2,3]),
...           offset=np.int_().itemsize,
...           dtype=np.int_) # offset = 1*itemsize, i.e. skip first element
array([2, 3])
```

```
polynomial.legendre.legx = array([0, 1])
```

```
ndarray(shape, dtype=None, buffer=None, offset=0, strides=None, order=None) -
```

```
ndarray(shape, dtype=np.float64, buffer=None, offset=0, strides=None, order=None)
```

An array object represents a multidimensional, homogeneous array of fixed-size items. An associated data-type object describes the format of each element in the array (its byte-order, how many bytes it occupies in memory, whether it is an integer, a floating point number, or something else, etc.)

Arrays should be constructed using *array*, *zeros* or *empty* (refer to the *See Also* section below). The parameters given here refer to a low-level method (*ndarray(...)*) for instantiating an array.

For more information, refer to the *numpy* module and examine the methods and attributes of an array.

Parameters

(for the `__new__` method; see Notes below)

shape

[tuple of ints] Shape of created array.

dtype

[data-type, optional] Any object that can be interpreted as a numpy data type. Default is *numpy.float64*.

buffer

[object exposing buffer interface, optional] Used to fill the array with data.

offset

[int, optional] Offset of array data in buffer.

strides

[tuple of ints, optional] Strides of data in memory.

order

[{'C', 'F'}, optional] Row-major (C-style) or column-major (Fortran-style) order.

Attributes**T**

[ndarray] Transpose of the array.

data

[buffer] The array's elements, in memory.

dtype

[dtype object] Describes the format of the elements in the array.

flags

[dict] Dictionary containing information related to memory use, e.g., 'C_CONTIGUOUS', 'OWNDATA', 'WRITEABLE', etc.

flat

[numpy.flatiter object] Flattened version of the array as an iterator. The iterator allows assignments, e.g., `x.flat = 3` (See `ndarray.flat` for assignment examples; TODO).

imag

[ndarray] Imaginary part of the array.

real

[ndarray] Real part of the array.

size

[int] Number of elements in the array.

itemsize

[int] The memory use of each array element in bytes.

nbytes

[int] The total number of bytes required to store the array data, i.e., `itemsize * size`.

ndim

[int] The array's number of dimensions.

shape

[tuple of ints] Shape of the array.

strides

[tuple of ints] The step-size required to move from one element to the next in memory. For example, a contiguous `(3, 4)` array of type `int16` in C-order has strides `(8, 2)`. This implies that to move from element to element in memory requires jumps of 2 bytes. To move from row-to-row, one needs to jump 8 bytes at a time (`2 * 4`).

ctypes

[ctypes object] Class containing properties of the array needed for interaction with ctypes.

base

[ndarray] If the array is a view into another array, that array is its *base* (unless that array is also a view). The *base* array is where the array data is actually stored.

See also:**`array`**

Construct an array.

`zeros`

Create an array, each element of which is zero.

empty

Create an array, but leave its allocated memory unchanged (i.e., it contains “garbage”).

dtype

Create a data-type.

numpy.typing.NDArray

An ndarray alias *generic* w.r.t. its *dtype.type*.

Notes

There are two modes of creating an array using `__new__`:

1. If *buffer* is None, then only *shape*, *dtype*, and *order* are used.
2. If *buffer* is an object exposing the buffer interface, then all keywords are interpreted.

No `__init__` method is needed because the array is fully initialized after the `__new__` method.

Examples

These examples illustrate the low-level *ndarray* constructor. Refer to the *See Also* section above for easier ways of constructing an ndarray.

First mode, *buffer* is None:

```
>>> import numpy as np
>>> np.ndarray(shape=(2,2), dtype=np.float64, order='F')
array([[0.0e+000, 0.0e+000], # random
       [      nan, 2.5e-323]])
```

Second mode:

```
>>> np.ndarray((2,), buffer=np.array([1,2,3]),
...           offset=np.int_().itemsize,
...           dtype=np.int_) # offset = 1*itemsize, i.e. skip first element
array([2, 3])
```

Arithmetic

<i>legadd</i> (c1, c2)	Add one Legendre series to another.
<i>legsub</i> (c1, c2)	Subtract one Legendre series from another.
<i>legmulx</i> (c)	Multiply a Legendre series by x.
<i>legmul</i> (c1, c2)	Multiply one Legendre series by another.
<i>legdiv</i> (c1, c2)	Divide one Legendre series by another.
<i>legpow</i> (c, pow[, maxpower])	Raise a Legendre series to a power.
<i>legval</i> (x, c[, tensor])	Evaluate a Legendre series at points x.
<i>legval2d</i> (x, y, c)	Evaluate a 2-D Legendre series at points (x, y).
<i>legval3d</i> (x, y, z, c)	Evaluate a 3-D Legendre series at points (x, y, z).
<i>legvalnd</i> (pts, c)	Evaluate an N-D Legendre series at points.
<i>leggrid2d</i> (x, y, c)	Evaluate a 2-D Legendre series on the Cartesian product of x and y.
<i>leggrid3d</i> (x, y, z, c)	Evaluate a 3-D Legendre series on the Cartesian product of x, y, and z.

`polynomial.legendre.legadd(c1, c2)`

Add one Legendre series to another.

Returns the sum of two Legendre series $c1 + c2$. The arguments are sequences of coefficients ordered from lowest order term to highest, i.e., $[1,2,3]$ represents the series $P_0 + 2P_1 + 3P_2$.

Parameters

c1, c2

[array_like] 1-D arrays of Legendre series coefficients ordered from low to high.

Returns

out

[ndarray] Array representing the Legendre series of their sum.

See also:

[*legsub*](#), [*legmulx*](#), [*legmul*](#), [*legdiv*](#), [*legpow*](#)

Notes

Unlike multiplication, division, etc., the sum of two Legendre series is a Legendre series (without having to “reproject” the result onto the basis set) so addition, just like that of “standard” polynomials, is simply “component-wise.”

Examples

```
>>> from numpy.polynomial import legendre as L
>>> c1 = (1, 2, 3)
>>> c2 = (3, 2, 1)
>>> L.legadd(c1, c2)
array([4., 4., 4.])
```

`polynomial.legendre.legsub(c1, c2)`

Subtract one Legendre series from another.

Returns the difference of two Legendre series $c1 - c2$. The sequences of coefficients are from lowest order term to highest, i.e., $[1,2,3]$ represents the series $P_0 + 2P_1 + 3P_2$.

Parameters

c1, c2

[array_like] 1-D arrays of Legendre series coefficients ordered from low to high.

Returns

out

[ndarray] Of Legendre series coefficients representing their difference.

See also:

[*legadd*](#), [*legmulx*](#), [*legmul*](#), [*legdiv*](#), [*legpow*](#)

Notes

Unlike multiplication, division, etc., the difference of two Legendre series is a Legendre series (without having to “reproject” the result onto the basis set) so subtraction, just like that of “standard” polynomials, is simply “component-wise.”

Examples

```
>>> from numpy.polynomial import legendre as L
>>> c1 = (1, 2, 3)
>>> c2 = (3, 2, 1)
>>> L.legsub(c1, c2)
array([-2.,  0.,  2.])
>>> L.legsub(c2, c1) # -C.legsub(c1, c2)
array([ 2.,  0., -2.])
```

`polynomial.legendre.legmulx(c)`

Multiply a Legendre series by x.

Multiply the Legendre series *c* by x, where x is the independent variable.

Parameters

c

[array_like] 1-D array of Legendre series coefficients ordered from low to high.

Returns

out

[ndarray] Array representing the result of the multiplication.

See also:

[*legadd*](#), [*legsub*](#), [*legmul*](#), [*legdiv*](#), [*legpow*](#)

Notes

The multiplication uses the recursion relationship for Legendre polynomials in the form

$$xP_i(x) = ((i + 1) * P_{i+1}(x) + i * P_{i-1}(x)) / (2i + 1)$$

Examples

```
>>> from numpy.polynomial import legendre as L
>>> L.legmulx([1, 2, 3])
array([ 0.66666667,  2.2,  1.33333333,  1.8]) # may vary
```

`polynomial.legendre.legmul(c1, c2)`

Multiply one Legendre series by another.

Returns the product of two Legendre series *c1* * *c2*. The arguments are sequences of coefficients, from lowest order “term” to highest, e.g., [1,2,3] represents the series $P_0 + 2P_1 + 3P_2$.

Parameters

c1, c2

[array_like] 1-D arrays of Legendre series coefficients ordered from low to high.

Returns**out**

[ndarray] Of Legendre series coefficients representing their product.

See also:*legadd, legsub, legmulx, legdiv, legpow***Notes**

In general, the (polynomial) product of two C-series results in terms that are not in the Legendre polynomial basis set. Thus, to express the product as a Legendre series, it is necessary to “reproject” the product onto said basis set, which may produce “unintuitive” (but correct) results; see Examples section below.

Examples

```
>>> from numpy.polynomial import legendre as L
>>> c1 = (1, 2, 3)
>>> c2 = (3, 2)
>>> L.legmul(c1, c2) # multiplication requires "reprojection"
array([ 4.33333333, 10.4          , 11.66666667,  3.6          ]) # may vary
```

polynomial.legendre.**legdiv**(c1, c2)

Divide one Legendre series by another.

Returns the quotient-with-remainder of two Legendre series $c1 / c2$. The arguments are sequences of coefficients from lowest order “term” to highest, e.g., [1,2,3] represents the series $P_0 + 2*P_1 + 3*P_2$.

Parameters**c1, c2**

[array_like] 1-D arrays of Legendre series coefficients ordered from low to high.

Returns**quo, rem**

[ndarrays] Of Legendre series coefficients representing the quotient and remainder.

See also:*legadd, legsub, legmulx, legmul, legpow***Notes**

In general, the (polynomial) division of one Legendre series by another results in quotient and remainder terms that are not in the Legendre polynomial basis set. Thus, to express these results as a Legendre series, it is necessary to “reproject” the results onto the Legendre basis set, which may produce “unintuitive” (but correct) results; see Examples section below.

Examples

```
>>> from numpy.polynomial import legendre as L
>>> c1 = (1, 2, 3)
>>> c2 = (3, 2, 1)
>>> L.legdiv(c1, c2) # quotient "intuitive," remainder not
(array([3.]), array([-8., -4.]))
>>> c2 = (0, 1, 2, 3)
>>> L.legdiv(c2, c1) # neither "intuitive"
(array([-0.07407407,  1.66666667]), array([-1.03703704, -2.51851852])) # may vary
```

`polynomial.legendre.legpow(c, pow, maxpower=16)`

Raise a Legendre series to a power.

Returns the Legendre series c raised to the power pow . The argument c is a sequence of coefficients ordered from low to high. i.e., $[1, 2, 3]$ is the series $P_0 + 2P_1 + 3P_2$.

Parameters

c

[array_like] 1-D array of Legendre series coefficients ordered from low to high.

pow

[integer] Power to which the series will be raised

maxpower

[integer, optional] Maximum power allowed. This is mainly to limit growth of the series to unmanageable size. Default is 16

Returns

coef

[ndarray] Legendre series of power.

See also:

[*legadd*](#), [*legsub*](#), [*legmulx*](#), [*legmul*](#), [*legdiv*](#)

`polynomial.legendre.legval(x, c, tensor=True)`

Evaluate a Legendre series at points x .

If c is of length $n + 1$, this function returns the value:

$$p(x) = c_0 * L_0(x) + c_1 * L_1(x) + \dots + c_n * L_n(x)$$

The parameter x is converted to an array only if it is a tuple or a list, otherwise it is treated as a scalar. In either case, either x or its elements must support multiplication and addition both with themselves and with the elements of c .

If c is a 1-D array, then $p(x)$ will have the same shape as x . If c is multidimensional, then the shape of the result depends on the value of *tensor*. If *tensor* is true the shape will be $c.shape[1:] + x.shape$. If *tensor* is false the shape will be $c.shape[1:]$. Note that scalars have shape $(,)$.

Trailing zeros in the coefficients will be used in the evaluation, so they should be avoided if efficiency is a concern.

Parameters

x

[array_like, compatible object] If x is a list or tuple, it is converted to an ndarray, otherwise it is left unchanged and treated as a scalar. In either case, x or its elements must support addition and multiplication with themselves and with the elements of c .

c
 [array_like] Array of coefficients ordered so that the coefficients for terms of degree n are contained in $c[n]$. If c is multidimensional the remaining indices enumerate multiple polynomials. In the two dimensional case the coefficients may be thought of as stored in the columns of c .

tensor
 [boolean, optional] If True, the shape of the coefficient array is extended with ones on the right, one for each dimension of x . Scalars have dimension 0 for this action. The result is that every column of coefficients in c is evaluated for every element of x . If False, x is broadcast over the columns of c for the evaluation. This keyword is useful when c is multidimensional. The default value is True.

Returns

values
 [ndarray, algebra_like] The shape of the return value is described above.

See also:

legval2d, leggrid2d, legval3d, leggrid3d

Notes

The evaluation uses Clenshaw recursion, aka synthetic division.

`polynomial.legendre.legval2d(x, y, c)`

Evaluate a 2-D Legendre series at points (x, y) .

This function returns the values:

$$p(x, y) = \sum_{i,j} c_{i,j} * L_i(x) * L_j(y)$$

The parameters x and y are converted to arrays only if they are tuples or a lists, otherwise they are treated as a scalars and they must have the same shape after conversion. In either case, either x and y or their elements must support multiplication and addition both with themselves and with the elements of c .

If c is a 1-D array a one is implicitly appended to its shape to make it 2-D. The shape of the result will be $c.shape[2:] + x.shape$.

Parameters

x, y
 [array_like, compatible objects] The two dimensional series is evaluated at the points (x, y) , where x and y must have the same shape. If x or y is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and if it isn't an ndarray it is treated as a scalar.

c
 [array_like] Array of coefficients ordered so that the coefficient of the term of multi-degree i, j is contained in $c[i, j]$. If c has dimension greater than two the remaining indices enumerate multiple sets of coefficients.

Returns

values
 [ndarray, compatible object] The values of the two dimensional Legendre series at points formed from pairs of corresponding values from x and y .

See also:

legval, leggrid2d, legval3d, leggrid3d`polynomial.legendre.legval3d(x, y, z, c)`

Evaluate a 3-D Legendre series at points (x, y, z).

This function returns the values:

$$p(x, y, z) = \sum_{i,j,k} c_{i,j,k} * L_i(x) * L_j(y) * L_k(z)$$

The parameters *x*, *y*, and *z* are converted to arrays only if they are tuples or a lists, otherwise they are treated as a scalars and they must have the same shape after conversion. In either case, either *x*, *y*, and *z* or their elements must support multiplication and addition both with themselves and with the elements of *c*.

If *c* has fewer than 3 dimensions, ones are implicitly appended to its shape to make it 3-D. The shape of the result will be *c*.shape[3:] + *x*.shape.

Parameters**x, y, z**

[array_like, compatible object] The three dimensional series is evaluated at the points (*x*, *y*, *z*), where *x*, *y*, and *z* must have the same shape. If any of *x*, *y*, or *z* is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and if it isn't an ndarray it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficient of the term of multi-degree *i,j,k* is contained in *c*[*i*, *j*, *k*]. If *c* has dimension greater than 3 the remaining indices enumerate multiple sets of coefficients.

Returns**values**

[ndarray, compatible object] The values of the multidimensional polynomial on points formed with triples of corresponding values from *x*, *y*, and *z*.

See also:

legval, legval2d, leggrid2d, leggrid3d`polynomial.legendre.legvalnd(pts, c)`

Evaluate an N-D Legendre series at points.

This function returns the values:

$$p(pts, c) = \sum_{i_1, i_2, \dots, i_n} c_{i_1, i_2, \dots, i_n} * P_{i_1}(x_1) * P_{i_2}(x_2) \dots P_{i_n}(x_n)$$

where $x_1, x_2, \dots, x_n = pts$. Note that *pts* may also be an (*n*, *m*) array.

The parameters in *pts* are converted to arrays only if they are tuples or lists, otherwise they are treated as scalars and they must have the same shape after conversion. In either case, either the elements of *pts* or their elements must support multiplication and addition both with themselves and with the elements of *c*.

If *c* has fewer than N dimensions, ones are implicitly appended to its shape to make it N-D. The shape of the result will be *c*.shape[N:] + *pts*[0].shape.

Parameters

pts

[tuple or list of array_like, compatible objects] The N-dimensional series is evaluated at the points $(x_1, x_2, \dots, x_n)$ provided in the *pts* iterable, where all elements must have the same shape. If any element is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and if it isn't an ndarray it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficient of the term of multi-degree $i, j, k, \dots$ is contained in $c[i, j, k, \dots]$. If *c* has dimension greater than N, the remaining indices enumerate multiple sets of coefficients.

Returns**values**

[ndarray, compatible object] The values of the multidimensional Legendre series on points formed with N-tuples of corresponding values from *pts*.

See also:

[*legval*](#), [*legval2d*](#), [*legval3d*](#)

`polynomial.legendre.leggrid2d(x, y, c)`

Evaluate a 2-D Legendre series on the Cartesian product of *x* and *y*.

This function returns the values:

$$p(a, b) = \sum_{i,j} c_{i,j} * L_i(a) * L_j(b)$$

where the points (a, b) consist of all pairs formed by taking *a* from *x* and *b* from *y*. The resulting points form a grid with *x* in the first dimension and *y* in the second.

The parameters *x* and *y* are converted to arrays only if they are tuples or a lists, otherwise they are treated as a scalars. In either case, either *x* and *y* or their elements must support multiplication and addition both with themselves and with the elements of *c*.

If *c* has fewer than two dimensions, ones are implicitly appended to its shape to make it 2-D. The shape of the result will be $c.shape[2:] + x.shape + y.shape$.

Parameters**x, y**

[array_like, compatible objects] The two dimensional series is evaluated at the points in the Cartesian product of *x* and *y*. If *x* or *y* is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and, if it isn't an ndarray, it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficient of the term of multi-degree i, j is contained in $c[i, j]$. If *c* has dimension greater than two the remaining indices enumerate multiple sets of coefficients.

Returns**values**

[ndarray, compatible object] The values of the two dimensional Chebyshev series at points in the Cartesian product of *x* and *y*.

See also:

[*legval*](#), [*legval2d*](#), [*legval3d*](#), [*leggrid3d*](#)

`polynomial.legendre.leggrid3d(x, y, z, c)`

Evaluate a 3-D Legendre series on the Cartesian product of x , y , and z .

This function returns the values:

$$p(a, b, c) = \sum_{i,j,k} c_{i,j,k} * L_i(a) * L_j(b) * L_k(c)$$

where the points (a, b, c) consist of all triples formed by taking a from x , b from y , and c from z . The resulting points form a grid with x in the first dimension, y in the second, and z in the third.

The parameters x , y , and z are converted to arrays only if they are tuples or a lists, otherwise they are treated as a scalars. In either case, either x , y , and z or their elements must support multiplication and addition both with themselves and with the elements of c .

If c has fewer than three dimensions, ones are implicitly appended to its shape to make it 3-D. The shape of the result will be $c.\text{shape}[3:] + x.\text{shape} + y.\text{shape} + z.\text{shape}$.

Parameters

x, y, z

[array_like, compatible objects] The three dimensional series is evaluated at the points in the Cartesian product of x , y , and z . If x , y , or z is a list or tuple, it is first converted to an ndarray, otherwise it is left unchanged and, if it isn't an ndarray, it is treated as a scalar.

c

[array_like] Array of coefficients ordered so that the coefficients for terms of degree i, j are contained in $c[i, j]$. If c has dimension greater than two the remaining indices enumerate multiple sets of coefficients.

Returns

values

[ndarray, compatible object] The values of the two dimensional polynomial at points in the Cartesian product of x and y .

See also:

[`legval`](#), [`legval2d`](#), [`leggrid2d`](#), [`legval3d`](#)

Calculus

<code>legder(c[, m, scl, axis])</code>	Differentiate a Legendre series.
<code>legint(c[, m, k, lbnd, scl, axis])</code>	Integrate a Legendre series.

`polynomial.legendre.legder(c, m=1, scl=1, axis=0)`

Differentiate a Legendre series.

Returns the Legendre series coefficients c differentiated m times along $axis$. At each iteration the result is multiplied by scl (the scaling factor is for use in a linear change of variable). The argument c is an array of coefficients from low to high degree along each axis, e.g., $[1,2,3]$ represents the series $1*L_0 + 2*L_1 + 3*L_2$ while $[[1,2],[1,2]]$ represents $1*L_0(x)*L_0(y) + 1*L_1(x)*L_0(y) + 2*L_0(x)*L_1(y) + 2*L_1(x)*L_1(y)$ if $axis=0$ is x and $axis=1$ is y .

Parameters

- c**
[array_like] Array of Legendre series coefficients. If *c* is multidimensional the different axis correspond to different variables with the degree in each axis given by the corresponding index.
- m**
[int, optional] Number of derivatives taken, must be non-negative. (Default: 1)
- scl**
[scalar, optional] Each differentiation is multiplied by *scl*. The end result is multiplication by *scl***m*. This is for use in a linear change of variable. (Default: 1)
- axis**
[int, optional] Axis over which the derivative is taken. (Default: 0).

Returns

- der**
[ndarray] Legendre series of the derivative.

See also:

[*legint*](#)

Notes

In general, the result of differentiating a Legendre series does not resemble the same operation on a power series. Thus the result of this function may be “unintuitive,” albeit correct; see Examples section below.

Examples

```
>>> from numpy.polynomial import legendre as L
>>> c = (1,2,3,4)
>>> L.legder(c)
array([ 6.,  9., 20.])
>>> L.legder(c, 3)
array([60.])
>>> L.legder(c, scl=-1)
array([ -6., -9., -20.])
>>> L.legder(c, 2,-1)
array([ 9., 60.])
```

`polynomial.legendre.legint` (*c*, *m*=1, *k*=[], *lbnd*=0, *scl*=1, *axis*=0)

Integrate a Legendre series.

Returns the Legendre series coefficients *c* integrated *m* times from *lbnd* along *axis*. At each iteration the resulting series is **multiplied** by *scl* and an integration constant, *k*, is added. The scaling factor is for use in a linear change of variable. (“Buyer beware”: note that, depending on what one is doing, one may want *scl* to be the reciprocal of what one might expect; for more information, see the Notes section below.) The argument *c* is an array of coefficients from low to high degree along each axis, e.g., [1,2,3] represents the series $L_0 + 2*L_1 + 3*L_2$ while [[1,2],[1,2]] represents $1*L_0(x)*L_0(y) + 1*L_1(x)*L_0(y) + 2*L_0(x)*L_1(y) + 2*L_1(x)*L_1(y)$ if *axis*=0 is *x* and *axis*=1 is *y*.

Parameters

- c**
[array_like] Array of Legendre series coefficients. If *c* is multidimensional the different axis correspond to different variables with the degree in each axis given by the corresponding index.

m
[int, optional] Order of integration, must be positive. (Default: 1)

k
[[], list, scalar], optional] Integration constant(s). The value of the first integral at `lbnd` is the first value in the list, the value of the second integral at `lbnd` is the second value, etc. If `k == []` (the default), all constants are set to zero. If `m == 1`, a single scalar can be given instead of a list.

lbnd
[scalar, optional] The lower bound of the integral. (Default: 0)

scl
[scalar, optional] Following each integration the result is *multiplied* by `scl` before the integration constant is added. (Default: 1)

axis
[int, optional] Axis over which the integral is taken. (Default: 0).

Returns

S
[ndarray] Legendre series coefficient array of the integral.

Raises**ValueError**

If `m < 0`, `len(k) > m`, `np.ndim(lbnd) != 0`, or `np.ndim(scl) != 0`.

See also:

[*legder*](#)

Notes

Note that the result of each integration is *multiplied* by `scl`. Why is this important to note? Say one is making a linear change of variable $u = ax + b$ in an integral relative to x . Then $dx = du/a$, so one will need to set `scl` equal to $1/a$ - perhaps not what one would have first thought.

Also note that, in general, the result of integrating a C-series needs to be “reprojected” onto the C-series basis set. Thus, typically, the result of this function is “unintuitive,” albeit correct; see Examples section below.

Examples

```
>>> from numpy.polynomial import legendre as L
>>> c = (1,2,3)
>>> L.legendre(c)
array([ 0.33333333,  0.4          ,  0.66666667,  0.6          ]) # may vary
>>> L.legendre(c, 3)
array([ 1.66666667e-02, -1.78571429e-02,  4.76190476e-02, # may vary
       -1.73472348e-18,  1.90476190e-02,  9.52380952e-03])
>>> L.legendre(c, k=3)
array([ 3.33333333,  0.4          ,  0.66666667,  0.6          ]) # may vary
>>> L.legendre(c, lbnd=-2)
array([ 7.33333333,  0.4          ,  0.66666667,  0.6          ]) # may vary
>>> L.legendre(c, scl=2)
array([ 0.66666667,  0.8          ,  1.33333333,  1.2          ]) # may vary
```

Misc Functions

<code>legfromroots</code> (roots)	Generate a Legendre series with given roots.
<code>legroots</code> (c)	Compute the roots of a Legendre series.
<code>legvander</code> (x, deg)	Pseudo-Vandermonde matrix of given degree.
<code>legvander2d</code> (x, y, deg)	Pseudo-Vandermonde matrix of given degrees.
<code>legvander3d</code> (x, y, z, deg)	Pseudo-Vandermonde matrix of given degrees.
<code>leggauss</code> (deg)	Gauss-Legendre quadrature.
<code>legweight</code> (x)	Weight function of the Legendre polynomials.
<code>legcompanion</code> (c)	Return the scaled companion matrix of c.
<code>legfit</code> (x, y, deg[, rcond, full, w])	Least squares fit of Legendre series to data.
<code>legtrim</code> (c[, tol])	Remove "small" "trailing" coefficients from a polynomial.
<code>legline</code> (off, scl)	Legendre series whose graph is a straight line.
<code>leg2poly</code> (c)	Convert a Legendre series to a polynomial.
<code>poly2leg</code> (pol)	Convert a polynomial to a Legendre series.

`polynomial.legendre.legfromroots` (roots)

Generate a Legendre series with given roots.

The function returns the coefficients of the polynomial

$$p(x) = (x - r_0) * (x - r_1) * \dots * (x - r_n),$$

in Legendre form, where the r_n are the roots specified in `roots`. If a zero has multiplicity n , then it must appear in `roots` n times. For instance, if 2 is a root of multiplicity three and 3 is a root of multiplicity 2, then `roots` looks something like [2, 2, 2, 3, 3]. The roots can appear in any order.

If the returned coefficients are c , then

$$p(x) = c_0 + c_1 * L_1(x) + \dots + c_n * L_n(x)$$

The coefficient of the last term is not generally 1 for monic polynomials in Legendre form.

Parameters**roots**

[array_like] Sequence containing the roots.

Returns**out**

[ndarray] 1-D array of coefficients. If all roots are real then `out` is a real array, if some of the roots are complex, then `out` is complex even if all the coefficients in the result are real (see Examples below).

See also:

`numpy.polynomial.polynomial.polyfromroots`
`numpy.polynomial.chebyshev.chebfromroots`
`numpy.polynomial.laguerre.lagfromroots`
`numpy.polynomial.hermite.hermfromroots`
`numpy.polynomial.hermite_e.hermefromroots`

Examples

```
>>> import numpy.polynomial.legendre as L
>>> L.legfromroots((-1,0,1)) # x^3 - x relative to the standard basis
array([ 0. , -0.4,  0. ,  0.4])
>>> j = complex(0,1)
>>> L.legfromroots((-j,j)) # x^2 + 1 relative to the standard basis
array([ 1.33333333+0.j,  0.00000000+0.j,  0.66666667+0.j]) # may vary
```

`polynomial.legendre.legroots(c)`

Compute the roots of a Legendre series.

Return the roots (a.k.a. “zeros”) of the polynomial

$$p(x) = \sum_i c[i] * L_i(x).$$

Parameters

c
[1-D array_like] 1-D array of coefficients.

Returns

out
[ndarray] Array of the roots of the series. If all the roots are real, then *out* is also real, otherwise it is complex.

See also:

`numpy.polynomial.polynomial.polyroots`
`numpy.polynomial.chebyshev.chebroots`
`numpy.polynomial.laguerre.lagroots`
`numpy.polynomial.hermite.hermroots`
`numpy.polynomial.hermite_e.hermroots`

Notes

The root estimates are obtained as the eigenvalues of the companion matrix, Roots far from the origin of the complex plane may have large errors due to the numerical instability of the series for such values. Roots with multiplicity greater than 1 will also show larger errors as the value of the series near such points is relatively insensitive to errors in the roots. Isolated roots near the origin can be improved by a few iterations of Newton’s method.

The Legendre series basis polynomials aren’t powers of x so the results of this function may seem unintuitive.

Examples

```
>>> import numpy.polynomial.legendre as leg
>>> leg.legroots((1, 2, 3, 4)) # 4L_3 + 3L_2 + 2L_1 + 1L_0, all real roots
array([-0.85099543, -0.11407192,  0.51506735]) # may vary
```

`polynomial.legendre.legvander(x, deg)`

Pseudo-Vandermonde matrix of given degree.

Returns the pseudo-Vandermonde matrix of degree *deg* and sample points *x*. The pseudo-Vandermonde matrix is defined by

$$V[... , i] = L_i(x)$$

where $0 \leq i \leq \text{deg}$. The leading indices of *V* index the elements of *x* and the last index is the degree of the Legendre polynomial.

If *c* is a 1-D array of coefficients of length $n + 1$ and *V* is the array $V = \text{legvander}(x, n)$, then $\text{np.dot}(V, c)$ and $\text{legval}(x, c)$ are the same up to roundoff. This equivalence is useful both for least squares fitting and for the evaluation of a large number of Legendre series of the same degree and sample points.

Parameters

x

[array_like] Array of points. The dtype is converted to float64 or complex128 depending on whether any of the elements are complex. If *x* is scalar it is converted to a 1-D array.

deg

[int] Degree of the resulting matrix.

Returns

vander

[ndarray] The pseudo-Vandermonde matrix. The shape of the returned matrix is $x.\text{shape} + (\text{deg} + 1,)$, where The last index is the degree of the corresponding Legendre polynomial. The dtype will be the same as the converted *x*.

`polynomial.legendre.legvander2d(x, y, deg)`

Pseudo-Vandermonde matrix of given degrees.

Returns the pseudo-Vandermonde matrix of degrees *deg* and sample points (x, y) . The pseudo-Vandermonde matrix is defined by

$$V[... , (\text{deg}[1] + 1) * i + j] = L_i(x) * L_j(y),$$

where $0 \leq i \leq \text{deg}[0]$ and $0 \leq j \leq \text{deg}[1]$. The leading indices of *V* index the points (x, y) and the last index encodes the degrees of the Legendre polynomials.

If $V = \text{legvander2d}(x, y, [\text{xdeg}, \text{ydeg}])$, then the columns of *V* correspond to the elements of a 2-D coefficient array *c* of shape $(\text{xdeg} + 1, \text{ydeg} + 1)$ in the order

$$c_{00}, c_{01}, c_{02}, \dots, c_{10}, c_{11}, c_{12}, \dots$$

and $\text{np.dot}(V, c.\text{flat})$ and $\text{legval2d}(x, y, c)$ will be the same up to roundoff. This equivalence is useful both for least squares fitting and for the evaluation of a large number of 2-D Legendre series of the same degrees and sample points.

Parameters

x, y

[array_like] Arrays of point coordinates, all of the same shape. The dtypes will be converted to either float64 or complex128 depending on whether any of the elements are complex. Scalars are converted to 1-D arrays.

deg

[list of ints] List of maximum degrees of the form $[x_deg, y_deg]$.

Returns

vander2d

[ndarray] The shape of the returned matrix is `x.shape + (order,)`, where `order = (deg[0] + 1) * (deg[1] + 1)`. The dtype will be the same as the converted `x` and `y`.

See also:

[*legvander*](#), [*legvander3d*](#), [*legval2d*](#), [*legval3d*](#)

`polynomial.legendre.legvander3d(x, y, z, deg)`

Pseudo-Vandermonde matrix of given degrees.

Returns the pseudo-Vandermonde matrix of degrees `deg` and sample points `(x, y, z)`. If `l, m, n` are the given degrees in `x, y, z`, then The pseudo-Vandermonde matrix is defined by

$$V[...,(m+1)(n+1)i + (n+1)j + k] = L_i(x) * L_j(y) * L_k(z),$$

where $0 \leq i \leq l, 0 \leq j \leq m$, and $0 \leq k \leq n$. The leading indices of `V` index the points `(x, y, z)` and the last index encodes the degrees of the Legendre polynomials.

If `V = legvander3d(x, y, z, [xdeg, ydeg, zdeg])`, then the columns of `V` correspond to the elements of a 3-D coefficient array `c` of shape `(xdeg + 1, ydeg + 1, zdeg + 1)` in the order

$$c_{000}, c_{001}, c_{002}, \dots, c_{010}, c_{011}, c_{012}, \dots$$

and `np.dot(V, c.flat)` and `legval3d(x, y, z, c)` will be the same up to roundoff. This equivalence is useful both for least squares fitting and for the evaluation of a large number of 3-D Legendre series of the same degrees and sample points.

Parameters**x, y, z**

[array_like] Arrays of point coordinates, all of the same shape. The dtypes will be converted to either float64 or complex128 depending on whether any of the elements are complex. Scalars are converted to 1-D arrays.

deg

[list of ints] List of maximum degrees of the form `[x_deg, y_deg, z_deg]`.

Returns**vander3d**

[ndarray] The shape of the returned matrix is `x.shape + (order,)`, where `order = (deg[0] + 1) * (deg[1] + 1) * (deg[2] + 1)`. The dtype will be the same as the converted `x, y`, and `z`.

See also:

[*legvander*](#), [*legvander3d*](#), [*legval2d*](#), [*legval3d*](#)

`polynomial.legendre.leggauss(deg)`

Gauss-Legendre quadrature.

Computes the sample points and weights for Gauss-Legendre quadrature. These sample points and weights will correctly integrate polynomials of degree $2 * deg - 1$ or less over the interval $[-1, 1]$ with the weight function $f(x) = 1$.

Parameters**deg**

[int] Number of sample points and weights. It must be ≥ 1 .

Returns

- x**
[ndarray] 1-D ndarray containing the sample points.
- y**
[ndarray] 1-D ndarray containing the weights.

Notes

The results have only been tested up to degree 100, higher degrees may be problematic. The weights are determined by using the fact that

$$w_k = c / (L'_n(x_k) * L_{n-1}(x_k))$$

where c is a constant independent of k and x_k is the k 'th root of L_n , and then scaling the results to get the right value when integrating 1.

`polynomial.legendre.legweight(x)`

Weight function of the Legendre polynomials.

The weight function is 1 and the interval of integration is $[-1, 1]$. The Legendre polynomials are orthogonal, but not normalized, with respect to this weight function.

Parameters

- x**
[array_like] Values at which the weight function will be computed.

Returns

- w**
[ndarray] The weight function at x .

`polynomial.legendre.legcompanion(c)`

Return the scaled companion matrix of c .

The basis polynomials are scaled so that the companion matrix is symmetric when c is a Legendre basis polynomial. This provides better eigenvalue estimates than the unscaled case and for basis polynomials the eigenvalues are guaranteed to be real if `numpy.linalg.eigvalsh` is used to obtain them.

Parameters

- c**
[array_like] 1-D array of Legendre series coefficients ordered from low to high degree.

Returns

- mat**
[ndarray] Scaled companion matrix of dimensions (deg, deg).

`polynomial.legendre.legfit(x, y, deg, rcond=None, full=False, w=None)`

Least squares fit of Legendre series to data.

Return the coefficients of a Legendre series of degree deg that is the least squares fit to the data values y given at points x . If y is 1-D the returned coefficients will also be 1-D. If y is 2-D multiple fits are done, one for each column of y , and the resulting coefficients are stored in the corresponding columns of a 2-D return. The fitted polynomial(s) are in the form

$$p(x) = c_0 + c_1 * L_1(x) + \dots + c_n * L_n(x),$$

where n is deg .

Parameters

- x**
[array_like, shape (M,)] x-coordinates of the M sample points ($x[i]$, $y[i]$).
- y**
[array_like, shape (M,) or (M, K)] y-coordinates of the sample points. Several data sets of sample points sharing the same x-coordinates can be fitted at once by passing in a 2D-array that contains one dataset per column.
- deg**
[int or 1-D array_like] Degree(s) of the fitting polynomials. If *deg* is a single integer all terms up to and including the *deg*'th term are included in the fit. For NumPy versions $\geq 1.11.0$ a list of integers specifying the degrees of the terms to include may be used instead.
- rcond**
[float, optional] Relative condition number of the fit. Singular values smaller than this relative to the largest singular value will be ignored. The default value is $\text{len}(x) \cdot \text{eps}$, where *eps* is the relative precision of the float type, about $2e-16$ in most cases.
- full**
[bool, optional] Switch determining nature of return value. When it is False (the default) just the coefficients are returned, when True diagnostic information from the singular value decomposition is also returned.
- w**
[array_like, shape (M,), optional] Weights. If not None, the weight $w[i]$ applies to the unsquared residual $y[i] - \hat{y}[i]$ at $x[i]$. Ideally the weights are chosen so that the errors of the products $w[i] \cdot y[i]$ all have the same variance. When using inverse-variance weighting, use $w[i] = 1/\text{sigma}(y[i])$. The default value is None.

Returns

- coef**
[ndarray, shape (M,) or (M, K)] Legendre coefficients ordered from low to high. If *y* was 2-D, the coefficients for the data in column *k* of *y* are in column *k*. If *deg* is specified as a list, coefficients for terms not included in the fit are set equal to zero in the returned *coef*.
- [residuals, rank, singular_values, rcond]**
[list] These values are only returned if `full == True`
- residuals – sum of squared residuals of the least squares fit
 - rank – the numerical rank of the scaled Vandermonde matrix
 - singular_values – singular values of the scaled Vandermonde matrix
 - rcond – value of *rcond*.

For more details, see [`numpy.linalg.lstsq`](#).

Warns**RankWarning**

The rank of the coefficient matrix in the least-squares fit is deficient. The warning is only raised if `full == False`. The warnings can be turned off by

```
>>> import warnings
>>> warnings.simplefilter('ignore', np.exceptions.RankWarning)
```

See also:

`numpy.polynomial.polynomial.polyfit`
`numpy.polynomial.chebyshev.chebfit`
`numpy.polynomial.laguerre.lagfit`
`numpy.polynomial.hermite.hermfit`
`numpy.polynomial.hermite_e.hermefit`
`legval`

Evaluates a Legendre series.

`legvander`

Vandermonde matrix of Legendre series.

`legweight`

Legendre weight function (= 1).

`numpy.linalg.lstsq`

Computes a least-squares fit from the matrix.

`scipy.interpolate.UnivariateSpline`

Computes spline fits.

Notes

The solution is the coefficients of the Legendre series p that minimizes the sum of the weighted squared errors

$$E = \sum_j w_j^2 * |y_j - p(x_j)|^2,$$

where w_j are the weights. This problem is solved by setting up as the (typically) overdetermined matrix equation

$$V(x) * c = w * y,$$

where V is the weighted pseudo Vandermonde matrix of x , c are the coefficients to be solved for, w are the weights, and y are the observed values. This equation is then solved using the singular value decomposition of V .

If some of the singular values of V are so small that they are neglected, then a *RankWarning* will be issued. This means that the coefficient values may be poorly determined. Using a lower order fit will usually get rid of the warning. The *rcond* parameter can also be set to a value smaller than its default, but the resulting fit may be spurious and have large contributions from roundoff error.

Fits using Legendre series are usually better conditioned than fits using power series, but much can depend on the distribution of the sample points and the smoothness of the data. If the quality of the fit is inadequate splines may be a good alternative.

References

[1]

`polynomial.legendre.legtrim(c, tol=0)`

Remove “small” “trailing” coefficients from a polynomial.

“Small” means “small in absolute value” and is controlled by the parameter *tol*; “trailing” means highest order coefficient(s), e.g., in $[0, 1, 1, 0, 0]$ (which represents $0 + x + x^2 + 0x^3 + 0x^4$) both the 3-rd and 4-th order coefficients would be “trimmed.”

Parameters

c

[array_like] 1-d array of coefficients, ordered from lowest order to highest.

tol

[number, optional] Trailing (i.e., highest order) elements with absolute value less than or equal to *tol* (default value is zero) are removed.

Returns**trimmed**

[ndarray] 1-d array with trailing zeros removed. If the resulting series would be empty, a series containing a single zero is returned.

Raises**ValueError**

If *tol* < 0

Examples

```
>>> from numpy.polynomial import polyutils as pu
>>> pu.trimcoef((0,0,3,0,5,0,0))
array([0., 0., 3., 0., 5.])
>>> pu.trimcoef((0,0,1e-3,0,1e-5,0,0),1e-3) # item == tol is trimmed
array([0.])
>>> i = complex(0,1) # works for complex
>>> pu.trimcoef((3e-4,1e-3*(1-i),5e-4,2e-5*(1+i)), 1e-3)
array([0.0003+0.j, 0.001 -0.001j])
```

`polynomial.legendre.legline` (*off*, *scl*)

Legendre series whose graph is a straight line.

Parameters**off, scl**

[scalars] The specified line is given by $\text{off} + \text{scl} \cdot x$.

Returns**y**

[ndarray] This module's representation of the Legendre series for $\text{off} + \text{scl} \cdot x$.

See also:

`numpy.polynomial.polynomial.polyline`
`numpy.polynomial.chebyshev.chebline`
`numpy.polynomial.laguerre.lagline`
`numpy.polynomial.hermite.hermline`
`numpy.polynomial.hermite_e.hermeline`

Examples

```
>>> import numpy.polynomial.legendre as L
>>> L.legline(3,2)
array([3, 2])
>>> L.legval(-3, L.legline(3,2)) # should be -3
-3.0
```

`polynomial.legendre.leg2poly(c)`

Convert a Legendre series to a polynomial.

Convert an array representing the coefficients of a Legendre series, ordered from lowest degree to highest, to an array of the coefficients of the equivalent polynomial (relative to the “standard” basis) ordered from lowest to highest degree.

Parameters

c

[array_like] 1-D array containing the Legendre series coefficients, ordered from lowest order term to highest.

Returns

pol

[ndarray] 1-D array containing the coefficients of the equivalent polynomial (relative to the “standard” basis) ordered from lowest order term to highest.

See also:

[*poly2leg*](#)

Notes

The easy way to do conversions between polynomial basis sets is to use the `convert` method of a class instance.

Examples

```
>>> from numpy import polynomial as P
>>> c = P.Legendre(range(4))
>>> c
Legendre([0., 1., 2., 3.], domain=[-1., 1.], window=[-1., 1.], symbol='x')
>>> p = c.convert(kind=P.Polynomial)
>>> p
Polynomial([-1. , -3.5,  3. ,  7.5], domain=[-1., 1.], window=[-1., ...
>>> P.legendre.leg2poly(range(4))
array([-1. , -3.5,  3. ,  7.5])
```

`polynomial.legendre.poly2leg(pol)`

Convert a polynomial to a Legendre series.

Convert an array representing the coefficients of a polynomial (relative to the “standard” basis) ordered from lowest degree to highest, to an array of the coefficients of the equivalent Legendre series, ordered from lowest to highest degree.

Parameters

pol

[array_like] 1-D array containing the polynomial coefficients

Returns

c

[ndarray] 1-D array containing the coefficients of the equivalent Legendre series.

See also:

[*leg2poly*](#)

Notes

The easy way to do conversions between polynomial basis sets is to use the `convert` method of a class instance.

Examples

```
>>> import numpy as np
>>> from numpy import polynomial as P
>>> p = P.Polynomial(np.arange(4))
>>> p
Polynomial([0., 1., 2., 3.], domain=[-1., 1.], window=[-1., 1.], ...)
>>> c = P.Legendre(P.legendre.poly2leg(p.coef))
>>> c
Legendre([ 1. , 3.25, 1. , 0.75], domain=[-1, 1], window=[-1, 1]) # may vary
```

See also

`numpy.polynomial`

Polyutils

Utility classes and functions for the polynomial modules.

This module provides: error and warning objects; a polynomial base class; and some routines used in both the *polynomial* and *chebyshev* modules.

Functions

<code>as_series(alist[, trim])</code>	Return argument as a list of 1-d arrays.
<code>trimseq(seq)</code>	Remove small Poly series coefficients.
<code>trimcoef(c[, tol])</code>	Remove "small" "trailing" coefficients from a polynomial.
<code>getdomain(x)</code>	Return a domain suitable for given abscissae.
<code>mapdomain(x, old, new)</code>	Apply linear map to input points.
<code>mapparms(old, new)</code>	Linear map parameters between domains.

`polynomial.polyutils.as_series (alist, trim=True)`

Return argument as a list of 1-d arrays.

The returned list contains array(s) of dtype double, complex double, or object. A 1-d argument of shape $(N,)$ is parsed into N arrays of size one; a 2-d argument of shape (M, N) is parsed into M arrays of size N (i.e., is “parsed by row”); and a higher dimensional array raises a Value Error if it is not first reshaped into either a 1-d or 2-d array.

Parameters

alist

[array_like] A 1- or 2-d array_like

trim

[boolean, optional] When True, trailing zeros are removed from the inputs. When False, the inputs are passed through intact.

Returns

[a1, a2,...]

[list of 1-D arrays] A copy of the input data as a list of 1-d arrays.

Raises**ValueError**Raised when `as_series` cannot convert its input to 1-d arrays, or at least one of the resulting arrays is empty.**Examples**

```
>>> import numpy as np
>>> from numpy.polynomial import polyutils as pu
>>> a = np.arange(4)
>>> pu.as_series(a)
[array([0.]), array([1.]), array([2.]), array([3.])]
>>> b = np.arange(6).reshape((2,3))
>>> pu.as_series(b)
[array([0., 1., 2.]), array([3., 4., 5.])]
```

```
>>> pu.as_series((1, np.arange(3), np.arange(2, dtype=np.float16)))
[array([1.]), array([0., 1., 2.]), array([0., 1.])]
```

```
>>> pu.as_series([2, [1.1, 0.]])
[array([2.]), array([1.1])]
```

```
>>> pu.as_series([2, [1.1, 0.]], trim=False)
[array([2.]), array([1.1, 0. ])]
```

`polynomial.polyutils.trimseq(seq)`

Remove small Poly series coefficients.

Parameters**seq**

[sequence] Sequence of Poly series coefficients.

Returns**series**

[sequence] Subsequence with trailing zeros removed. If the resulting sequence would be empty, return the first element. The returned sequence may or may not be a view.

Notes

Do not lose the type info if the sequence contains unknown objects.

`polynomial.polyutils.trimcoef(c, tol=0)`

Remove “small” “trailing” coefficients from a polynomial.

“Small” means “small in absolute value” and is controlled by the parameter *tol*; “trailing” means highest order coefficient(s), e.g., in `[0, 1, 1, 0, 0]` (which represents $0 + x + x^2 + 0x^3 + 0x^4$) both the 3-rd and 4-th order coefficients would be “trimmed.”

Parameters

c

[array_like] 1-d array of coefficients, ordered from lowest order to highest.

tol

[number, optional] Trailing (i.e., highest order) elements with absolute value less than or equal to *tol* (default value is zero) are removed.

Returns**trimmed**

[ndarray] 1-d array with trailing zeros removed. If the resulting series would be empty, a series containing a single zero is returned.

Raises**ValueError**

If *tol* < 0

Examples

```
>>> from numpy.polynomial import polyutils as pu
>>> pu.trimcoef((0,0,3,0,5,0,0))
array([0., 0., 3., 0., 5.])
>>> pu.trimcoef((0,0,1e-3,0,1e-5,0,0),1e-3) # item == tol is trimmed
array([0.])
>>> i = complex(0,1) # works for complex
>>> pu.trimcoef((3e-4,1e-3*(1-i),5e-4,2e-5*(1+i)), 1e-3)
array([0.0003+0.j, 0.001 -0.001j])
```

`polynomial.polyutils.getdomain(x)`

Return a domain suitable for given abscissae.

Find a domain suitable for a polynomial or Chebyshev series defined at the values supplied.

Parameters**x**

[array_like] 1-d array of abscissae whose domain will be determined.

Returns**domain**

[ndarray] 1-d array containing two values. If the inputs are complex, then the two returned points are the lower left and upper right corners of the smallest rectangle (aligned with the axes) in the complex plane containing the points *x*. If the inputs are real, then the two points are the ends of the smallest interval containing the points *x*.

See also:

[*mapparms*](#), [*mapdomain*](#)

Examples

```
>>> import numpy as np
>>> from numpy.polynomial import polyutils as pu
>>> points = np.arange(4)**2 - 5; points
array([-5, -4, -1,  4])
>>> pu.getdomain(points)
array([-5.,  4.])
>>> c = np.exp(complex(0,1)*np.pi*np.arange(12)/6) # unit circle
>>> pu.getdomain(c)
array([-1.-1.j,  1.+1.j])
```

`polynomial.polyutils.mapdomain(x, old, new)`

Apply linear map to input points.

The linear map $\text{offset} + \text{scale} * x$ that maps the domain *old* to the domain *new* is applied to the points *x*.

Parameters

x

[array_like] Points to be mapped. If *x* is a subtype of ndarray the subtype will be preserved.

old, new

[array_like] The two domains that determine the map. Each must (successfully) convert to 1-d arrays containing precisely two values.

Returns

x_out

[ndarray] Array of points of the same shape as *x*, after application of the linear map between the two domains.

See also:

[*getdomain*](#), [*mapparms*](#)

Notes

Effectively, this implements:

$$x_{\text{out}} = \text{new}[0] + m(x - \text{old}[0])$$

where

$$m = \frac{\text{new}[1] - \text{new}[0]}{\text{old}[1] - \text{old}[0]}$$

Examples

```
>>> import numpy as np
>>> from numpy.polynomial import polyutils as pu
>>> old_domain = (-1,1)
>>> new_domain = (0,2*np.pi)
>>> x = np.linspace(-1,1,6); x
array([-1. , -0.6, -0.2,  0.2,  0.6,  1. ])
>>> x_out = pu.mapdomain(x, old_domain, new_domain); x_out
```

(continues on next page)

(continued from previous page)

```
array([ 0.          ,  1.25663706,  2.51327412,  3.76991118,  5.02654825, # may vary
        6.28318531])
>>> x = pu.mapdomain(x_out, new_domain, old_domain)
array([0., 0., 0., 0., 0., 0.]
```

Also works for complex numbers (and thus can be used to map any line in the complex plane to any other line therein).

```
>>> i = complex(0,1)
>>> old = (-1 - i, 1 + i)
>>> new = (-1 + i, 1 - i)
>>> z = np.linspace(old[0], old[1], 6); z
array([-1. -1.j , -0.6-0.6j, -0.2-0.2j,  0.2+0.2j,  0.6+0.6j,  1. +1.j ])
>>> new_z = pu.mapdomain(z, old, new); new_z
array([-1.0+1.j , -0.6+0.6j, -0.2+0.2j,  0.2-0.2j,  0.6-0.6j,  1.0-1.j ]) # may vary
↪ vary
```

`polynomial.polyutils.mapparms (old, new)`

Linear map parameters between domains.

Return the parameters of the linear map $\text{offset} + \text{scale} \cdot x$ that maps *old* to *new* such that `old[i] -> new[i]`, $i = 0, 1$.

Parameters

old, new

[array_like] Domains. Each domain must (successfully) convert to a 1-d array containing precisely two values.

Returns

offset, scale

[scalars] The map $L(x) = \text{offset} + \text{scale} \cdot x$ maps the first domain to the second.

See also:

[*getdomain, mapdomain*](#)

Notes

Also works for complex numbers, and thus can be used to calculate the parameters required to map any line in the complex plane to any other line therein.

Examples

```
>>> from numpy.polynomial import polyutils as pu
>>> pu.mapparms((-1,1), (-1,1))
(0.0, 1.0)
>>> pu.mapparms((1,-1), (-1,1))
(-0.0, -1.0)
>>> i = complex(0,1)
>>> pu.mapparms((-i,-1), (1,i))
((1+1j), (1-0j))
```

Documentation for legacy polynomials

Poly1d

Basics

<code>poly1d(c_or_r[, r, variable])</code>	A one-dimensional polynomial class.
<code>polyval(p, x)</code>	Evaluate a polynomial at specific values.
<code>poly(seq_of_zeros)</code>	Find the coefficients of a polynomial with the given sequence of roots.
<code>roots(p)</code>	Return the roots of a polynomial with coefficients given in <code>p</code> .

class `numpy.poly1d(c_or_r, r=False, variable=None)`
A one-dimensional polynomial class.

Note: This forms part of the old polynomial API. Since version 1.4, the new polynomial API defined in `numpy.polynomial` is preferred. A summary of the differences can be found in the [transition guide](#).

A convenience class, used to encapsulate “natural” operations on polynomials so that said operations may take on their customary form in code (see Examples).

Parameters

- c_or_r**
[array_like] The polynomial’s coefficients, in decreasing powers, or if the value of the second parameter is True, the polynomial’s roots (values where the polynomial evaluates to 0). For example, `poly1d([1, 2, 3])` returns an object that represents $x^2 + 2x + 3$, whereas `poly1d([1, 2, 3], True)` returns one that represents $(x - 1)(x - 2)(x - 3) = x^3 - 6x^2 + 11x - 6$.
- r**
[bool, optional] If True, `c_or_r` specifies the polynomial’s roots; the default is False.
- variable**
[str, optional] Changes the variable used when printing `p` from `x` to `variable` (see Examples).

Attributes

- c**
The polynomial coefficients
- coef**
The polynomial coefficients
- coefficients**
The polynomial coefficients
- coeffs**
The polynomial coefficients
- o**
The order or degree of the polynomial
- order**
The order or degree of the polynomial

r
The roots of the polynomial, where `self(x) == 0`

roots
The roots of the polynomial, where `self(x) == 0`

variable
The name of the polynomial variable

Methods

<code>__call__(val)</code>	Call self as a function.
<code>deriv([m])</code>	Return a derivative of this polynomial.
<code>integ([m, k])</code>	Return an antiderivative (indefinite integral) of this polynomial.

method

`poly1d.__call__(val)`
Call self as a function.

method

`poly1d.deriv(m=1)`
Return a derivative of this polynomial.
Refer to [polyder](#) for full documentation.

See also:

[polyder](#)
equivalent function

method

`poly1d.integ(m=1, k=0)`
Return an antiderivative (indefinite integral) of this polynomial.
Refer to [polyint](#) for full documentation.

See also:

[polyint](#)
equivalent function

Examples

```
>>> import numpy as np
```

Construct the polynomial $x^2 + 2x + 3$:

```
>>> import numpy as np
```

```
>>> p = np.poly1d([1, 2, 3])
>>> print(np.poly1d(p))
      2
1 x + 2 x + 3
```

Evaluate the polynomial at $x = 0.5$:

```
>>> p(0.5)
4.25
```

Find the roots:

```
>>> p.r
array([-1.+1.41421356j, -1.-1.41421356j])
>>> p(p.r)
array([-4.44089210e-16+0.j, -4.44089210e-16+0.j]) # may vary
```

These numbers in the previous line represent (0, 0) to machine precision

Show the coefficients:

```
>>> p.c
array([1, 2, 3])
```

Display the order (the leading zero-coefficients are removed):

```
>>> p.order
2
```

Show the coefficient of the k -th power in the polynomial (which is equivalent to `p.c[-(i+1)]`):

```
>>> p[1]
2
```

Polynomials can be added, subtracted, multiplied, and divided (returns quotient and remainder):

```
>>> p * p
poly1d([ 1,  4, 10, 12,  9])
```

```
>>> (p**3 + 4) / p
(poly1d([ 1.,  4., 10., 12.,  9.]), poly1d([4.]))
```

`asarray(p)` gives the coefficient array, so polynomials can be used in all functions that accept arrays:

```
>>> p**2 # square of polynomial
poly1d([ 1,  4, 10, 12,  9])
```

```
>>> np.square(p) # square of individual coefficients
array([1, 4, 9])
```

The variable used in the string representation of p can be modified, using the `variable` parameter:

```
>>> p = np.poly1d([1,2,3], variable='z')
>>> print(p)
      2
1 z + 2 z + 3
```

Construct a polynomial from its roots:

```
>>> np.poly1d([1, 2], True)
poly1d([ 1., -3.,  2.] )
```

This is the same polynomial as obtained by:

```
>>> np.poly1d([1, -1]) * np.poly1d([1, -2])
poly1d([ 1, -3,  2])
```

`numpy.polyval` (*p*, *x*)

Evaluate a polynomial at specific values.

Note: This forms part of the old polynomial API. Since version 1.4, the new polynomial API defined in `numpy.polynomial` is preferred. A summary of the differences can be found in the [transition guide](#).

If *p* is of length *N*, this function returns the value:

```
p[0]*x**(N-1) + p[1]*x**(N-2) + ... + p[N-2]*x + p[N-1]
```

If *x* is a sequence, then *p* (*x*) is returned for each element of *x*. If *x* is another polynomial then the composite polynomial *p* (*x* (*t*)) is returned.

Parameters

p

[array_like or poly1d object] 1D array of polynomial coefficients (including coefficients equal to zero) from highest degree to the constant term, or an instance of poly1d.

x

[array_like or poly1d object] A number, an array of numbers, or an instance of poly1d, at which to evaluate *p*.

Returns

values

[ndarray or poly1d] If *x* is a poly1d instance, the result is the composition of the two polynomials, i.e., *x* is “substituted” in *p* and the simplified result is returned. In addition, the type of *x* - array_like or poly1d - governs the type of the output: *x* array_like => *values* array_like, *x* a poly1d object => *values* is also.

See also:

`poly1d`

A polynomial class.

Notes

Horner's scheme [1] is used to evaluate the polynomial. Even so, for polynomials of high degree the values may be inaccurate due to rounding errors. Use carefully.

If *x* is a subtype of `ndarray` the return value will be of the same type.

References

[1]

Examples

```
>>> import numpy as np
>>> np.polyval([3,0,1], 5) # 3 * 5**2 + 0 * 5**1 + 1
76
>>> np.polyval([3,0,1], np.poly1d(5))
poly1d([76])
>>> np.polyval(np.poly1d([3,0,1]), 5)
76
>>> np.polyval(np.poly1d([3,0,1]), np.poly1d(5))
poly1d([76])
```

`numpy.poly(seq_of_zeros)`

Find the coefficients of a polynomial with the given sequence of roots.

Note: This forms part of the old polynomial API. Since version 1.4, the new polynomial API defined in `numpy.polynomial` is preferred. A summary of the differences can be found in the [transition guide](#).

Returns the coefficients of the polynomial whose leading coefficient is one for the given sequence of zeros (multiple roots must be included in the sequence as many times as their multiplicity; see Examples). A square matrix (or array, which will be treated as a matrix) can also be given, in which case the coefficients of the characteristic polynomial of the matrix are returned.

Parameters

`seq_of_zeros`

[array_like, shape (N,) or (N, N)] A sequence of polynomial roots, or a square array or matrix object.

Returns

`c`

[ndarray] 1D array of polynomial coefficients from highest to lowest degree:

$c[0] * x^{(N)} + c[1] * x^{(N-1)} + \dots + c[N-1] * x + c[N]$ where $c[0]$ always equals 1.

Raises

ValueError

If input is the wrong shape (the input must be a 1-D or square 2-D array).

See also:

`polyval`

Compute polynomial values.

`roots`

Return the roots of a polynomial.

`polyfit`

Least squares polynomial fit.

poly1d

A one-dimensional polynomial class.

Notes

Specifying the roots of a polynomial still leaves one degree of freedom, typically represented by an undetermined leading coefficient. [1] In the case of this function, that coefficient - the first one in the returned array - is always taken as one. (If for some reason you have one other point, the only automatic way presently to leverage that information is to use `polyfit`.)

The characteristic polynomial, $p_a(t)$, of an n -by- n matrix **A** is given by

$$p_a(t) = \det(t\mathbf{I} - \mathbf{A}),$$

where **I** is the n -by- n identity matrix. [2]

References

[1], [2]

Examples

Given a sequence of a polynomial's zeros:

```
>>> import numpy as np
```

```
>>> np.poly((0, 0, 0)) # Multiple root example
array([1., 0., 0., 0.])
```

The line above represents $z^3 + 0z^2 + 0z + 0$.

```
>>> np.poly((-1./2, 0, 1./2))
array([ 1. ,  0. , -0.25,  0.  ])
```

The line above represents $z^3 - z/4$

```
>>> np.poly((np.random.random(1)[0], 0, np.random.random(1)[0]))
array([ 1.          , -0.77086955,  0.08618131,  0.          ]) # random
```

Given a square array object:

```
>>> P = np.array([[0, 1./3], [-1./2, 0]])
>>> np.poly(P)
array([1.          ,  0.          ,  0.16666667])
```

Note how in all cases the leading coefficient is always 1.

`numpy.roots(p)`

Return the roots of a polynomial with coefficients given in `p`.

Note: This forms part of the old polynomial API. Since version 1.4, the new polynomial API defined in `numpy.polynomial` is preferred. A summary of the differences can be found in the [transition guide](#).

The values in the rank-1 array p are coefficients of a polynomial. If the length of p is $n+1$ then the polynomial is described by:

$$p[0] * x^n + p[1] * x^{(n-1)} + \dots + p[n-1]*x + p[n]$$

Parameters

p
[array_like] Rank-1 array of polynomial coefficients.

Returns

out
[ndarray] An array containing the roots of the polynomial.

Raises

ValueError
When p cannot be converted to a rank-1 array.

See also:

poly
Find the coefficients of a polynomial with a given sequence of roots.

polyval
Compute polynomial values.

polyfit
Least squares polynomial fit.

poly1d
A one-dimensional polynomial class.

Notes

The algorithm relies on computing the eigenvalues of the companion matrix [1].

References

[1]

Examples

```
>>> import numpy as np
>>> coeff = [3.2, 2, 1]
>>> np.roots(coeff)
array([-0.3125+0.46351241j, -0.3125-0.46351241j])
```

Fitting

<code>polyfit(x, y, deg[, rcond, full, w, cov])</code>	Least squares polynomial fit.
--	-------------------------------

`numpy.polyfit(x, y, deg, rcond=None, full=False, w=None, cov=False)`

Least squares polynomial fit.

Note: This forms part of the old polynomial API. Since version 1.4, the new polynomial API defined in `numpy.polynomial` is preferred. A summary of the differences can be found in the [transition guide](#).

Fit a polynomial $p[0] * x^{deg} + \dots + p[deg]$ of degree *deg* to points (*x*, *y*). Returns a vector of coefficients *p* that minimises the squared error in the order *deg*, *deg*-1, ... 0.

The `Polynomial.fit` class method is recommended for new code as it is more stable numerically. See the documentation of the method for more information.

Parameters

- x**
[array_like, shape (M,)] x-coordinates of the M sample points (`x[i]`, `y[i]`).
- y**
[array_like, shape (M,) or (M, K)] y-coordinates of the sample points. Several data sets of sample points sharing the same x-coordinates can be fitted at once by passing in a 2D-array that contains one dataset per column.
- deg**
[int] Degree of the fitting polynomial
- rcond**
[float, optional] Relative condition number of the fit. Singular values smaller than this relative to the largest singular value will be ignored. The default value is `len(x)*eps`, where `eps` is the relative precision of the float type, about 2e-16 in most cases.
- full**
[bool, optional] Switch determining nature of return value. When it is `False` (the default) just the coefficients are returned, when `True` diagnostic information from the singular value decomposition is also returned.
- w**
[array_like, shape (M,), optional] Weights. If not `None`, the weight `w[i]` applies to the unsquared residual `y[i] - y_hat[i]` at `x[i]`. Ideally the weights are chosen so that the errors of the products `w[i]*y[i]` all have the same variance. When using inverse-variance weighting, use `w[i] = 1/sigma(y[i])`. The default value is `None`.
- cov**
[bool or str, optional] If given and not `False`, return not just the estimate but also its covariance matrix. By default, the covariance are scaled by `chi2/dof`, where `dof = M - (deg + 1)`, i.e., the weights are presumed to be unreliable except in a relative sense and everything is scaled such that the reduced chi2 is unity. This scaling is omitted if `cov='unscaled'`, as is relevant for the case that the weights are `w = 1/sigma`, with `sigma` known to be a reliable estimate of the uncertainty.

Returns

p

[ndarray, shape (deg + 1,) or (deg + 1, K)] Polynomial coefficients, highest power first. If *y* was 2-D, the coefficients for *k*-th data set are in `p[:, k]`.

residuals, rank, singular_values, rcond

These values are only returned if `full == True`

- residuals – sum of squared residuals of the least squares fit
- rank – the effective rank of the scaled Vandermonde coefficient matrix
- singular_values – singular values of the scaled Vandermonde coefficient matrix
- rcond – value of *rcond*.

For more details, see [`numpy.linalg.lstsq`](#).

V

[ndarray, shape (deg + 1, deg + 1) or (deg + 1, deg + 1, K)] Present only if `full == False` and `cov == True`. The covariance matrix of the polynomial coefficient estimates. The diagonal of this matrix are the variance estimates for each coefficient. If *y* is a 2-D array, then the covariance matrix for the *k*-th data set are in `V[:, :, k]`

Warns**RankWarning**

The rank of the coefficient matrix in the least-squares fit is deficient. The warning is only raised if `full == False`.

The warnings can be turned off by

```
>>> import warnings
>>> warnings.simplefilter('ignore', np.exceptions.RankWarning)
```

See also:**[`polyval`](#)**

Compute polynomial values.

[`linalg.lstsq`](#)

Computes a least-squares fit.

[`scipy.interpolate.UnivariateSpline`](#)

Computes spline fits.

Notes

The solution minimizes the squared error

$$E = \sum_{j=0}^k |p(x_j) - y_j|^2$$

in the equations:

```
x[0]**n * p[0] + ... + x[0] * p[n-1] + p[n] = y[0]
x[1]**n * p[0] + ... + x[1] * p[n-1] + p[n] = y[1]
...
x[k]**n * p[0] + ... + x[k] * p[n-1] + p[n] = y[k]
```

The coefficient matrix of the coefficients p is a Vandermonde matrix.

`polyfit` issues a `RankWarning` when the least-squares fit is badly conditioned. This implies that the best fit is not well-defined due to numerical error. The results may be improved by lowering the polynomial degree or by replacing x by $x - x.\text{mean}()$. The `rcond` parameter can also be set to a value smaller than its default, but the resulting fit may be spurious: including contributions from the small singular values can add numerical noise to the result.

Note that fitting polynomial coefficients is inherently badly conditioned when the degree of the polynomial is large or the interval of sample points is badly centered. The quality of the fit should always be checked in these cases. When polynomial fits are not satisfactory, splines may be a good alternative.

References

[1], [2]

Examples

```
>>> import numpy as np
>>> import warnings
>>> x = np.array([0.0, 1.0, 2.0, 3.0, 4.0, 5.0])
>>> y = np.array([0.0, 0.8, 0.9, 0.1, -0.8, -1.0])
>>> z = np.polyfit(x, y, 3)
>>> z
array([ 0.08703704, -0.81349206,  1.69312169, -0.03968254]) # may vary
```

It is convenient to use `poly1d` objects for dealing with polynomials:

```
>>> p = np.poly1d(z)
>>> p(0.5)
0.6143849206349179 # may vary
>>> p(3.5)
-0.34732142857143039 # may vary
>>> p(10)
22.579365079365115 # may vary
```

High-order polynomials may oscillate wildly:

```
>>> with warnings.catch_warnings():
...     warnings.simplefilter('ignore', np.exceptions.RankWarning)
...     p30 = np.poly1d(np.polyfit(x, y, 30))
...
>>> p30(4)
-0.800000000000000204 # may vary
>>> p30(5)
-0.999999999999999445 # may vary
>>> p30(4.5)
-0.10547061179440398 # may vary
```

Illustration:

```
>>> import matplotlib.pyplot as plt
>>> xp = np.linspace(-2, 6, 100)
>>> _ = plt.plot(x, y, '.', xp, p(xp), '-', xp, p30(xp), '--')
>>> plt.ylim(-2, 2)
>>> plt.show()
```

Calculus

<code>polyder(p[, m])</code>	Return the derivative of the specified order of a polynomial.
<code>polyint(p[, m, k])</code>	Return an antiderivative (indefinite integral) of a polynomial.

`numpy.polyder(p, m=1)`
Return the derivative of the specified order of a polynomial.

Note: This forms part of the old polynomial API. Since version 1.4, the new polynomial API defined in `numpy.polynomial` is preferred. A summary of the differences can be found in the [transition guide](#).

Parameters

- p**
[poly1d or sequence] Polynomial to differentiate. A sequence is interpreted as polynomial coefficients, see `poly1d`.
- m**
[int, optional] Order of differentiation (default: 1)

Returns

- der**
[poly1d] A new polynomial representing the derivative.

See also:

`polyint`
Anti-derivative of a polynomial.

poly1d

Class for one-dimensional polynomials.

Examples

The derivative of the polynomial $x^3 + x^2 + x^1 + 1$ is:

```
>>> import numpy as np
```

```
>>> p = np.poly1d([1,1,1,1])
>>> p2 = np.polyder(p)
>>> p2
poly1d([3, 2, 1])
```

which evaluates to:

```
>>> p2(2.)
17.0
```

We can verify this, approximating the derivative with $(f(x+h) - f(x))/h$:

```
>>> (p(2. + 0.001) - p(2.)) / 0.001
17.007000999997857
```

The fourth-order derivative of a 3rd-order polynomial is zero:

```
>>> np.polyder(p, 2)
poly1d([6, 2])
>>> np.polyder(p, 3)
poly1d([6])
>>> np.polyder(p, 4)
poly1d([0])
```

`numpy.polyint` (*p*, *m=1*, *k=None*)

Return an antiderivative (indefinite integral) of a polynomial.

Note: This forms part of the old polynomial API. Since version 1.4, the new polynomial API defined in `numpy.polynomial` is preferred. A summary of the differences can be found in the [transition guide](#).

The returned order m antiderivative P of polynomial p satisfies $\frac{d^m}{dx^m}P(x) = p(x)$ and is defined up to $m - 1$ integration constants k . The constants determine the low-order polynomial part

$$\frac{k_{m-1}}{0!}x^0 + \dots + \frac{k_0}{(m-1)!}x^{m-1}$$

of P so that $P^{(j)}(0) = k_{m-j-1}$.

Parameters

p

[array_like or poly1d] Polynomial to integrate. A sequence is interpreted as polynomial coefficients, see `poly1d`.

m

[int, optional] Order of the antiderivative. (Default: 1)

k

[list of m scalars or scalar, optional] Integration constants. They are given in the order of integration: those corresponding to highest-order terms come first.

If `None` (default), all constants are assumed to be zero. If $m = 1$, a single scalar can be given instead of a list.

See also:

polyder

derivative of a polynomial

poly1d.integ

equivalent method

Examples

The defining property of the antiderivative:

```
>>> import numpy as np
```

```
>>> p = np.poly1d([1,1,1])
>>> P = np.polyint(p)
>>> P
poly1d([ 0.33333333,  0.5          ,  1.          ,  0.          ]) # may vary
>>> np.polyder(P) == p
True
```

The integration constants default to zero, but can be specified:

```
>>> P = np.polyint(p, 3)
>>> P(0)
0.0
>>> np.polyder(P)(0)
0.0
>>> np.polyder(P, 2)(0)
0.0
>>> P = np.polyint(p, 3, k=[6,5,3])
>>> P
poly1d([ 0.01666667,  0.04166667,  0.16666667,  3. ,  5. ,  3. ]) # may vary
```

Note that $3 = 6 / 2!$, and that the constants are given in the order of integrations. Constant of the highest-order polynomial term comes first:

```
>>> np.polyder(P, 2)(0)
6.0
>>> np.polyder(P, 1)(0)
5.0
>>> P(0)
3.0
```

Arithmetic

<code>polyadd(a1, a2)</code>	Find the sum of two polynomials.
<code>polydiv(u, v)</code>	Returns the quotient and remainder of polynomial division.
<code>polymul(a1, a2)</code>	Find the product of two polynomials.
<code>polysub(a1, a2)</code>	Difference (subtraction) of two polynomials.

`numpy.polyadd(a1, a2)`

Find the sum of two polynomials.

Note: This forms part of the old polynomial API. Since version 1.4, the new polynomial API defined in `numpy.polynomial` is preferred. A summary of the differences can be found in the [transition guide](#).

Returns the polynomial resulting from the sum of two input polynomials. Each input must be either a `poly1d` object or a 1D sequence of polynomial coefficients, from highest to lowest degree.

Parameters

a1, a2

[array_like or `poly1d` object] Input polynomials.

Returns

out

[ndarray or `poly1d` object] The sum of the inputs. If either input is a `poly1d` object, then the output is also a `poly1d` object. Otherwise, it is a 1D array of polynomial coefficients from highest to lowest degree.

See also:

[`poly1d`](#)

A one-dimensional polynomial class.

[`poly`](#), [`polyadd`](#), [`polyder`](#), [`polydiv`](#), [`polyfit`](#), [`polyint`](#), [`polysub`](#), [`polyval`](#)

Examples

```
>>> import numpy as np
>>> np.polyadd([1, 2], [9, 5, 4])
array([9, 6, 6])
```

Using `poly1d` objects:

```
>>> p1 = np.poly1d([1, 2])
>>> p2 = np.poly1d([9, 5, 4])
>>> print(p1)
1 x + 2
>>> print(p2)
      2
9 x + 5 x + 4
>>> print(np.polyadd(p1, p2))
      2
9 x + 6 x + 6
```

`numpy.polydiv(u, v)`

Returns the quotient and remainder of polynomial division.

Note: This forms part of the old polynomial API. Since version 1.4, the new polynomial API defined in [numpy.polynomial](#) is preferred. A summary of the differences can be found in the [transition guide](#).

The input arrays are the coefficients (including any coefficients equal to zero) of the “numerator” (dividend) and “denominator” (divisor) polynomials, respectively.

Parameters

u
[array_like or poly1d] Dividend polynomial’s coefficients.

v
[array_like or poly1d] Divisor polynomial’s coefficients.

Returns

q
[ndarray] Coefficients, including those equal to zero, of the quotient.

r
[ndarray] Coefficients, including those equal to zero, of the remainder.

See also:

[poly](#), [polyadd](#), [polyder](#), [polydiv](#), [polyfit](#), [polyint](#), [polymul](#), [polysub](#),
[polyval](#)

Notes

Both *u* and *v* must be 0-d or 1-d (*ndim* = 0 or 1), but *u.ndim* need not equal *v.ndim*. In other words, all four possible combinations - *u.ndim* = *v.ndim* = 0, *u.ndim* = *v.ndim* = 1, *u.ndim* = 1, *v.ndim* = 0, and *u.ndim* = 0, *v.ndim* = 1 - work.

Examples

$$\frac{3x^2 + 5x + 2}{2x + 1} = 1.5x + 1.75, \text{remainder } 0.25$$

```
>>> import numpy as np
```

```
>>> x = np.array([3.0, 5.0, 2.0])
>>> y = np.array([2.0, 1.0])
>>> np.polydiv(x, y)
(array([1.5 , 1.75]), array([0.25]))
```

`numpy.polymul(a1, a2)`

Find the product of two polynomials.

Note: This forms part of the old polynomial API. Since version 1.4, the new polynomial API defined in [numpy.polynomial](#) is preferred. A summary of the differences can be found in the [transition guide](#).

Finds the polynomial resulting from the multiplication of the two input polynomials. Each input must be either a `poly1d` object or a 1D sequence of polynomial coefficients, from highest to lowest degree.

Parameters**a1, a2**[array_like or `poly1d` object] Input polynomials.**Returns****out**[ndarray or `poly1d` object] The polynomial resulting from the multiplication of the inputs. If either inputs is a `poly1d` object, then the output is also a `poly1d` object. Otherwise, it is a 1D array of polynomial coefficients from highest to lowest degree.**See also:****`poly1d`**

A one-dimensional polynomial class.

**`poly`, `polyadd`, `polyder`, `polydiv`, `polyfit`, `polyint`, `polysub`, `polyval`
`convolve`**Array convolution. Same output as `polymul`, but has parameter for overlap mode.**Examples**

```
>>> import numpy as np
>>> np.polymul([1, 2, 3], [9, 5, 1])
array([ 9, 23, 38, 17,  3])
```

Using `poly1d` objects:

```
>>> p1 = np.poly1d([1, 2, 3])
>>> p2 = np.poly1d([9, 5, 1])
>>> print(p1)
      2
  1 x + 2 x + 3
>>> print(p2)
      2
  9 x + 5 x + 1
>>> print(np.polymul(p1, p2))
      4      3      2
  9 x + 23 x + 38 x + 17 x + 3
```

`numpy.polysub(a1, a2)`

Difference (subtraction) of two polynomials.

Note: This forms part of the old polynomial API. Since version 1.4, the new polynomial API defined in `numpy.polynomial` is preferred. A summary of the differences can be found in the [transition guide](#).

Given two polynomials *a1* and *a2*, returns $a1 - a2$. *a1* and *a2* can be either array_like sequences of the polynomials' coefficients (including coefficients equal to zero), or `poly1d` objects.

Parameters**a1, a2**[array_like or `poly1d`] Minuend and subtrahend polynomials, respectively.

Returns**out**[ndarray or poly1d] Array or *poly1d* object of the difference polynomial's coefficients.

See also:

polyval, *polydiv*, *polymul*, *polyadd***Examples**

$$(2x^2 + 10x - 2) - (3x^2 + 10x - 4) = (-x^2 + 2)$$

```
>>> import numpy as np
```

```
>>> np.polysub([2, 10, -2], [3, 10, -4])
array([-1,  0,  2])
```

1.4.15 Set routines

Making proper sets

<i>unique</i> (ar[, return_index, return_inverse, ...])	Find the unique elements of an array.
<i>unique_all</i> (x)	Find the unique elements of an array, and counts, inverse, and indices.
<i>unique_counts</i> (x)	Find the unique elements and counts of an input array <i>x</i> .
<i>unique_inverse</i> (x)	Find the unique elements of <i>x</i> and indices to reconstruct <i>x</i> .
<i>unique_values</i> (x)	Returns the unique elements of an input array <i>x</i> .

`numpy.unique_all(x)`

Find the unique elements of an array, and counts, inverse, and indices.

This function is an Array API compatible alternative to:

```
np.unique(x, return_index=True, return_inverse=True,
         return_counts=True, equal_nan=False, sorted=False)
```

but returns a namedtuple for easier access to each output.

Note: This function currently always returns a sorted result, however, this could change in any NumPy minor release.

Parameters**x**

[array_like] Input array. It will be flattened if it is not already 1-D.

Returns

out

[namedtuple] The result containing:

- values - The unique elements of an input array.
- indices - The first occurring indices for each unique element.
- inverse_indices - The indices from the set of unique elements that reconstruct x .
- counts - The corresponding counts for each unique element.

See also:

unique

Find the unique elements of an array.

Examples

```
>>> import numpy as np
>>> x = [1, 1, 2]
>>> uniq = np.unique_all(x)
>>> uniq.values
array([1, 2])
>>> uniq.indices
array([0, 2])
>>> uniq.inverse_indices
array([0, 0, 1])
>>> uniq.counts
array([2, 1])
```

`numpy.unique_counts(x)`

Find the unique elements and counts of an input array x .

This function is an Array API compatible alternative to:

```
np.unique(x, return_counts=True, equal_nan=False, sorted=False)
```

but returns a namedtuple for easier access to each output.

Note: This function currently always returns a sorted result, however, this could change in any NumPy minor release.

Parameters

x

[array_like] Input array. It will be flattened if it is not already 1-D.

Returns

out

[namedtuple] The result containing:

- values - The unique elements of an input array.
- counts - The corresponding counts for each unique element.

See also:

unique

Find the unique elements of an array.

Examples

```
>>> import numpy as np
>>> x = [1, 1, 2]
>>> uniq = np.unique_counts(x)
>>> uniq.values
array([1, 2])
>>> uniq.counts
array([2, 1])
```

`numpy.unique_inverse(x)`

Find the unique elements of x and indices to reconstruct x .

This function is an Array API compatible alternative to:

```
np.unique(x, return_inverse=True, equal_nan=False, sorted=False)
```

but returns a namedtuple for easier access to each output.

Note: This function currently always returns a sorted result, however, this could change in any NumPy minor release.

Parameters

x

[array_like] Input array. It will be flattened if it is not already 1-D.

Returns

out

[namedtuple] The result containing:

- **values** - The unique elements of an input array.
- **inverse_indices** - The indices from the set of unique elements that reconstruct x .

See also:

unique

Find the unique elements of an array.

Examples

```
>>> import numpy as np
>>> x = [1, 1, 2]
>>> uniq = np.unique_inverse(x)
>>> uniq.values
array([1, 2])
>>> uniq.inverse_indices
array([0, 0, 1])
```

`numpy.unique_values(x)`

Returns the unique elements of an input array *x*.

This function is an Array API compatible alternative to:

```
np.unique(x, equal_nan=False, sorted=False)
```

Changed in version 2.3: The algorithm was changed to a faster one that does not rely on sorting, and hence the results are no longer implicitly sorted.

Parameters

x

[array_like] Input array. It will be flattened if it is not already 1-D.

Returns

out

[ndarray] The unique elements of an input array.

See also:

[*unique*](#)

Find the unique elements of an array.

Examples

```
>>> import numpy as np
>>> np.unique_values([1, 1, 2])
array([1, 2]) # may vary
```

Boolean operations

<code>intersect1d(ar1, ar2[, assume_unique, ...])</code>	Find the intersection of two arrays.
<code>isin(element, test_elements[, ...])</code>	Calculates element in test_elements, broadcasting over <i>element</i> only.
<code>setdiff1d(ar1, ar2[, assume_unique])</code>	Find the set difference of two arrays.
<code>setxor1d(ar1, ar2[, assume_unique])</code>	Find the set exclusive-or of two arrays.
<code>union1d(ar1, ar2)</code>	Find the union of two arrays.

`numpy.intersect1d(ar1, ar2, assume_unique=False, return_indices=False)`

Find the intersection of two arrays.

Return the sorted, unique values that are in both of the input arrays.

Parameters

ar1, ar2

[array_like] Input arrays. Will be flattened if not already 1D.

assume_unique

[bool] If True, the input arrays are both assumed to be unique, which can speed up the calculation. If True but *ar1* or *ar2* are not unique, incorrect results and out-of-bounds indices could result. Default is False.

return_indices

[bool] If True, the indices which correspond to the intersection of the two arrays are returned. The first instance of a value is used if there are multiple. Default is False.

Returns**intersect1d**

[ndarray] Sorted 1D array of common and unique elements.

comm1

[ndarray] The indices of the first occurrences of the common values in *ar1*. Only provided if *return_indices* is True.

comm2

[ndarray] The indices of the first occurrences of the common values in *ar2*. Only provided if *return_indices* is True.

Examples

```
>>> import numpy as np
>>> np.intersect1d([1, 3, 4, 3], [3, 1, 2, 1])
array([1, 3])
```

To intersect more than two arrays, use `functools.reduce`:

```
>>> from functools import reduce
>>> reduce(np.intersect1d, ([1, 3, 4, 3], [3, 1, 2, 1], [6, 3, 4, 2]))
array([3])
```

To return the indices of the values common to the input arrays along with the intersected values:

```
>>> x = np.array([1, 1, 2, 3, 4])
>>> y = np.array([2, 1, 4, 6])
>>> xy, x_ind, y_ind = np.intersect1d(x, y, return_indices=True)
>>> x_ind, y_ind
(array([0, 2, 4]), array([1, 0, 2]))
>>> xy, x[x_ind], y[y_ind]
(array([1, 2, 4]), array([1, 2, 4]), array([1, 2, 4]))
```

`numpy.isin(element, test_elements, assume_unique=False, invert=False, *, kind=None)`

Calculates *element* in *test_elements*, broadcasting over *element* only. Returns a boolean array of the same shape as *element* that is True where an element of *element* is in *test_elements* and False otherwise.

Parameters**element**

[array_like] Input array.

test_elements

[array_like] The values against which to test each value of *element*. This argument is flattened if it is an array or array_like. See notes for behavior with non-array-like parameters.

assume_unique

[bool, optional] If True, the input arrays are both assumed to be unique, which can speed up the calculation. Default is False.

invert

[bool, optional] If True, the values in the returned array are inverted, as if calculating *element*

not in test_elements. Default is False. `np.isin(a, b, invert=True)` is equivalent to (but faster than) `np.invert(np.isin(a, b))`.

kind

[{None, 'sort', 'table'}, optional] The algorithm to use. This will not affect the final result, but will affect the speed and memory use. The default, None, will select automatically based on memory considerations.

- If 'sort', will use a mergesort-based approach. This will have a memory usage of roughly 6 times the sum of the sizes of *element* and *test_elements*, not accounting for size of dtypes.
- If 'table', will use a lookup table approach similar to a counting sort. This is only available for boolean and integer arrays. This will have a memory usage of the size of *element* plus the max-min value of *test_elements*. *assume_unique* has no effect when the 'table' option is used.
- If None, will automatically choose 'table' if the required memory allocation is less than or equal to 6 times the sum of the sizes of *element* and *test_elements*, otherwise will use 'sort'. This is done to not use a large amount of memory by default, even though 'table' may be faster in most cases. If 'table' is chosen, *assume_unique* will have no effect.

Returns

isin

[ndarray, bool] Has the same shape as *element*. The values *element*[*isin*] are in *test_elements*.

Notes

isin is an element-wise function version of the python keyword *in*. `isin(a, b)` is roughly equivalent to `np.array([item in b for item in a])` if *a* and *b* are 1-D sequences.

element and *test_elements* are converted to arrays if they are not already. If *test_elements* is a set (or other non-sequence collection) it will be converted to an object array with one element, rather than an array of the values contained in *test_elements*. This is a consequence of the *array* constructor's way of handling non-sequence collections. Converting the set to a list usually gives the desired behavior.

Using `kind='table'` tends to be faster than `kind='sort'` if the following relationship is true: $\log_{10}(\text{len}(\text{test_elements})) > (\log_{10}(\text{max}(\text{test_elements}) - \text{min}(\text{test_elements})) - 2.27) / 0.927$, but may use greater memory. The default value for *kind* will be automatically selected based only on memory usage, so one may manually set `kind='table'` if memory constraints can be relaxed.

Examples

```
>>> import numpy as np
>>> element = 2*np.arange(4).reshape((2, 2))
>>> element
array([[0, 2],
       [4, 6]])
>>> test_elements = [1, 2, 4, 8]
>>> mask = np.isin(element, test_elements)
>>> mask
array([[False,  True],
       [ True, False]])
>>> element[mask]
array([2, 4])
```

The indices of the matched values can be obtained with *nonzero*:

```
>>> np.nonzero(mask)
(array([0, 1]), array([1, 0]))
```

The test can also be inverted:

```
>>> mask = np.isin(element, test_elements, invert=True)
>>> mask
array([[ True, False],
       [False,  True]])
>>> element[mask]
array([0, 6])
```

Because of how `array` handles sets, the following does not work as expected:

```
>>> test_set = {1, 2, 4, 8}
>>> np.isin(element, test_set)
array([[False, False],
       [False, False]])
```

Casting the set to a list gives the expected result:

```
>>> np.isin(element, list(test_set))
array([[False,  True],
       [ True, False]])
```

`numpy.setdiff1d(ar1, ar2, assume_unique=False)`

Find the set difference of two arrays.

Return the unique values in *ar1* that are not in *ar2*.

Parameters

ar1

[array_like] Input array.

ar2

[array_like] Input comparison array.

assume_unique

[bool] If True, the input arrays are both assumed to be unique, which can speed up the calculation. Default is False.

Returns

setdiff1d

[ndarray] 1D array of values in *ar1* that are not in *ar2*. The result is sorted when *assume_unique=False*, but otherwise only sorted if the input is sorted.

Examples

```
>>> import numpy as np
>>> a = np.array([1, 2, 3, 2, 4, 1])
>>> b = np.array([3, 4, 5, 6])
>>> np.setdiff1d(a, b)
array([1, 2])
```

`numpy.setxor1d(ar1, ar2, assume_unique=False)`

Find the set exclusive-or of two arrays.

Return the sorted, unique values that are in only one (not both) of the input arrays.

Parameters

ar1, ar2

[array_like] Input arrays.

assume_unique

[bool] If True, the input arrays are both assumed to be unique, which can speed up the calculation. Default is False.

Returns

setxor1d

[ndarray] Sorted 1D array of unique values that are in only one of the input arrays.

Examples

```
>>> import numpy as np
>>> a = np.array([1, 2, 3, 2, 4])
>>> b = np.array([2, 3, 5, 7, 5])
>>> np.setxor1d(a,b)
array([1, 4, 5, 7])
```

`numpy.union1d(ar1, ar2)`

Find the union of two arrays.

Return the unique, sorted array of values that are in either of the two input arrays.

Parameters

ar1, ar2

[array_like] Input arrays. They are flattened if they are not already 1D.

Returns

union1d

[ndarray] Unique, sorted union of the input arrays.

Examples

```
>>> import numpy as np
>>> np.union1d([-1, 0, 1], [-2, 0, 2])
array([-2, -1, 0, 1, 2])
```

To find the union of more than two arrays, use `functools.reduce`:

```
>>> from functools import reduce
>>> reduce(np.union1d, ([1, 3, 4, 3], [3, 1, 2, 1], [6, 3, 4, 2]))
array([1, 2, 3, 4, 6])
```

1.4.16 Sorting, searching, and counting

Sorting

<code>sort(a[, axis, kind, order, stable, descending])</code>	Return a sorted copy of an array.
<code>lexsort(keys[, axis])</code>	Perform an indirect stable sort using a sequence of keys.
<code>argsort(a[, axis, kind, order, stable, ...])</code>	Returns the indices that would sort an array.
<code>ndarray.sort([axis, kind, order, stable, ...])</code>	Sort an array in-place.
<code>sort_complex(a)</code>	Sort a complex array using the real part first, then the imaginary part.
<code>partition(a, kth[, axis, kind, order])</code>	Return a partitioned copy of an array.
<code>argpartition(a, kth[, axis, kind, order])</code>	Perform an indirect partition along the given axis using the algorithm specified by the <i>kind</i> keyword.

`numpy.sort(a, axis=-1, kind=None, order=None, *, stable=None, descending=<no value>)`

Return a sorted copy of an array.

Parameters

a

[array_like] Array to be sorted.

axis

[int or None, optional] Axis along which to sort. If None, the array is flattened before sorting. The default is -1, which sorts along the last axis.

kind

[['quicksort', 'mergesort', 'heapsort', 'stable'], optional] Sorting algorithm. The default is 'quicksort'. Note that both 'stable' and 'mergesort' use timsort or radix sort under the covers and, in general, the actual implementation will vary with data type. The 'mergesort' option is retained for backwards compatibility.

order

[str or list of str, optional] When *a* is an array with fields defined, this argument specifies which fields to compare first, second, etc. A single field can be specified as a string, and not all fields need be specified, but unspecified fields will still be used, in the order in which they come up in the dtype, to break ties.

stable

[bool, optional] Sort stability. If True, the returned array will maintain the relative order of a values which compare as equal. If False or None, this is not guaranteed. Internally, this option selects `kind='stable'`. Default: None.

New in version 2.0.0.

descending

[bool, optional] Sort order. If True, the returned array will be sorted in descending order. If False or None, the returned array will be sorted in ascending order. Values that are NaN are sorted to the end for both orders. Default: None.

New in version 2.5.0.

Returns

sorted_array

[ndarray] Array of the same type and shape as *a*.

See also:

`ndarray.sort`

Method to sort an array in-place.

`argsort`

Indirect sort.

`lexsort`

Indirect stable sort on multiple keys.

`searchsorted`

Find elements in a sorted array.

`partition`

Partial sort.

Notes

The various sorting algorithms are characterized by their average speed, worst case performance, work space size, and whether they are stable. A stable sort keeps items with the same key in the same relative order. The four algorithms implemented in NumPy have the following properties:

kind	speed	worst case	work space	stable
'quicksort'	1	$O(n^2)$	0	no
'heapsort'	3	$O(n \log(n))$	0	no
'mergesort'	2	$O(n \log(n))$	$\sim n/2$	yes
'timsort'	2	$O(n \log(n))$	$\sim n/2$	yes

Note: The datatype determines which of 'mergesort' or 'timsort' is actually used, even if 'mergesort' is specified. User selection at a finer scale is not currently available.

For performance, `sort` makes a temporary copy if needed to make the data [contiguous](#) in memory along the sort axis. For even better performance and reduced memory consumption, ensure that the array is already contiguous along the sort axis.

The sort order for complex numbers is lexicographic. If both the real and imaginary parts are non-nan then the order is determined by the real parts except when they are equal, in which case the order is determined by the imaginary parts.

Previous to numpy 1.4.0 sorting real and complex arrays containing nan values led to undefined behaviour. In numpy versions $\geq 1.4.0$ nan values are sorted to the end. The extended sort order is:

- Real: [R, nan]
- Complex: [R + Rj, R + nanj, nan + Rj, nan + nanj]

where R is a non-nan real value. Complex values with the same nan placements are sorted according to the non-nan part if it exists. Non-nan values are sorted as before.

`quicksort` has been changed to: [introsort](#). When sorting does not make enough progress it switches to `heapsort`. This implementation makes `quicksort` $O(n \log(n))$ in the worst case.

'stable' automatically chooses the best stable sorting algorithm for the data type being sorted. It, along with 'mergesort' is currently mapped to [timsort](#) or [radix sort](#) depending on the data type. API forward compatibility currently limits the ability to select the implementation and it is hardwired for the different data types.

Timsort is added for better performance on already or nearly sorted data. On random data timsort is almost identical to mergesort. It is now used for stable sort while quicksort is still the default sort if none is chosen. For timsort details, refer to [CPython listsort.txt](#) ‘mergesort’ and ‘stable’ are mapped to radix sort for integer data types. Radix sort is an $O(n)$ sort instead of $O(n \log n)$.

NaN now sorts to the end of arrays for consistency with NaN.

Examples

```
>>> import numpy as np
>>> a = np.array([[1,4],[3,1]])
>>> np.sort(a)                                # sort along the last axis
array([[1, 4],
       [1, 3]])
>>> np.sort(a, axis=None)                    # sort the flattened array
array([1, 1, 3, 4])
>>> np.sort(a, axis=0)                      # sort along the first axis
array([[1, 1],
       [3, 4]])
```

Use the *order* keyword to specify a field to use when sorting a structured array:

```
>>> dtype = [('name', 'S10'), ('height', float), ('age', int)]
>>> values = [('Arthur', 1.8, 41), ('Lancelot', 1.9, 38),
...          ('Galahad', 1.7, 38)]
>>> a = np.array(values, dtype=dtype)        # create a structured array
>>> np.sort(a, order='height')
array([('Galahad', 1.7, 38), ('Arthur', 1.8, 41),
      ('Lancelot', 1.8999999999999999, 38)],
      dtype=[('name', '<S10'), ('height', '<f8'), ('age', '<i4')])
```

Sort by age, then height if ages are equal:

```
>>> np.sort(a, order=['age', 'height'])
array([('Galahad', 1.7, 38), ('Lancelot', 1.8999999999999999, 38),
      ('Arthur', 1.8, 41)],
      dtype=[('name', '<S10'), ('height', '<f8'), ('age', '<i4')])
```

`numpy.lexsort(keys, axis=-1)`

Perform an indirect stable sort using a sequence of keys.

Given multiple sorting keys, `lexsort` returns an array of integer indices that describes the sort order by multiple keys. The last key in the sequence is used for the primary sort order, ties are broken by the second-to-last key, and so on.

Parameters

keys

[(k, m, n, ...) array-like] The *k* keys to be sorted. The *last* key (e.g. the last row if *keys* is a 2D array) is the primary sort key. Each element of *keys* along the zeroth axis must be an array-like object of the same shape.

axis

[int, optional] Axis to be indirectly sorted. By default, sort over the last axis of each sequence. Separate slices along *axis* sorted over independently; see last example.

Returns

indices

[(m, n, ...) ndarray of ints] Array of indices that sort the keys along the specified axis.

See also:

argsort

Indirect sort.

ndarray.sort

In-place sort.

sort

Return a sorted copy of an array.

Examples

Sort names: first by surname, then by name.

```
>>> import numpy as np
>>> surnames = ('Hertz', 'Galilei', 'Hertz')
>>> first_names = ('Heinrich', 'Galileo', 'Gustav')
>>> ind = np.lexsort((first_names, surnames))
>>> ind
array([1, 2, 0])
```

```
>>> [surnames[i] + ", " + first_names[i] for i in ind]
['Galilei, Galileo', 'Hertz, Gustav', 'Hertz, Heinrich']
```

Sort according to two numerical keys, first by elements of *a*, then breaking ties according to elements of *b*:

```
>>> a = [1, 5, 1, 4, 3, 4, 4] # First sequence
>>> b = [9, 4, 0, 4, 0, 2, 1] # Second sequence
>>> ind = np.lexsort((b, a)) # Sort by `a`, then by `b`
>>> ind
array([2, 0, 4, 6, 5, 3, 1])
>>> [(a[i], b[i]) for i in ind]
[(1, 0), (1, 9), (3, 0), (4, 1), (4, 2), (4, 4), (5, 4)]
```

Compare against *argsort*, which would sort each key independently.

```
>>> np.argsort((b, a), kind='stable')
array([[2, 4, 6, 5, 1, 3, 0],
       [0, 2, 4, 3, 5, 6, 1]])
```

To sort lexicographically with *argsort*, we would need to provide a structured array.

```
>>> x = np.array([(ai, bi) for ai, bi in zip(a, b)],
...               dtype = np.dtype([('x', int), ('y', int)]))
>>> np.argsort(x) # or np.argsort(x, order=('x', 'y'))
array([2, 0, 4, 6, 5, 3, 1])
```

The zeroth axis of *keys* always corresponds with the sequence of keys, so 2D arrays are treated just like other sequences of keys.

```
>>> arr = np.asarray([b, a])
>>> ind2 = np.lexsort(arr)
>>> np.testing.assert_equal(ind2, ind)
```

Accordingly, the *axis* parameter refers to an axis of *each* key, not of the *keys* argument itself. For instance, the array *arr* is treated as a sequence of two 1-D keys, so specifying *axis=0* is equivalent to using the default axis, *axis=-1*.

```
>>> np.testing.assert_equal(np.lexsort(arr, axis=0),
...                          np.lexsort(arr, axis=-1))
```

For higher-dimensional arrays, the *axis* parameter begins to matter. The resulting array has the same shape as each key, and the values are what we would expect if *lexsort* were performed on corresponding slices of the keys independently. For instance,

```
>>> x = [[1, 2, 3, 4],
...      [4, 3, 2, 1],
...      [2, 1, 4, 3]]
>>> y = [[2, 2, 1, 1],
...      [1, 2, 1, 2],
...      [1, 1, 2, 1]]
>>> np.lexsort((x, y), axis=1)
array([[2, 3, 0, 1],
       [2, 0, 3, 1],
       [1, 0, 3, 2]])
```

Each row of the result is what we would expect if we were to perform *lexsort* on the corresponding row of the keys:

```
>>> for i in range(3):
...     print(np.lexsort((x[i], y[i])))
[2 3 0 1]
[2 0 3 1]
[1 0 3 2]
```

`numpy.argsort` (*a*, *axis=-1*, *kind=None*, *order=None*, *, *stable=None*, *descending=<no value>*)

Returns the indices that would sort an array.

Perform an indirect sort along the given axis using the algorithm specified by the *kind* keyword. It returns an array of indices of the same shape as *a* that index data along the given axis in sorted order.

Parameters

a

[array_like] Array to sort.

axis

[int or None, optional] Axis along which to sort. The default is -1 (the last axis). If None, the flattened array is used.

kind

[{'quicksort', 'mergesort', 'heapsort', 'stable'}, optional] Sorting algorithm. The default is 'quicksort'. Note that both 'stable' and 'mergesort' use timsort under the covers and, in general, the actual implementation will vary with data type. The 'mergesort' option is retained for backwards compatibility.

order

[str or list of str, optional] When *a* is an array with fields defined, this argument specifies which fields to compare first, second, etc. A single field can be specified as a string, and not all fields need be specified, but unspecified fields will still be used, in the order in which they come up in the dtype, to break ties.

stable

[bool, optional] Sort stability. If `True`, the returned array will maintain the relative order of a values which compare as equal. If `False` or `None`, this is not guaranteed. Internally, this option selects `kind='stable'`. Default: `None`.

New in version 2.0.0.

descending

[bool, optional] Sort order. If `True`, the returned array will be sorted in descending order. If `False` or `None`, the returned array will be sorted in ascending order. Values that are NaN are sorted to the end for both orders. Default: `None`.

New in version 2.5.0.

Returns**index_array**

[ndarray, int] Array of indices that sort *a* along the specified *axis*. If *a* is one-dimensional, `a[index_array]` yields a sorted *a*. More generally, `np.take_along_axis(a, index_array, axis=axis)` always yields the sorted *a*, irrespective of dimensionality.

See also:***sort***

Describes sorting algorithms used.

lexsort

Indirect stable sort with multiple keys.

ndarray.sort

Inplace sort.

argsort

Indirect partial sort.

take_along_axis

Apply `index_array` from `argsort` to an array as if by calling `sort`.

Notes

See *sort* for notes on the different sorting algorithms.

As of NumPy 1.4.0 *argsort* works with real/complex arrays containing nan values. The enhanced sort order is documented in *sort*.

Examples

One dimensional array:

```
>>> import numpy as np
>>> x = np.array([3, 1, 2])
>>> np.argsort(x)
array([1, 2, 0])
```

Two-dimensional array:

```
>>> x = np.array([[0, 3], [2, 2]])
>>> x
array([[0, 3],
       [2, 2]])
```

```
>>> ind = np.argsort(x, axis=0) # sorts along first axis (down)
>>> ind
array([[0, 1],
       [1, 0]])
>>> np.take_along_axis(x, ind, axis=0) # same as np.sort(x, axis=0)
array([[0, 2],
       [2, 3]])
```

```
>>> ind = np.argsort(x, axis=1) # sorts along last axis (across)
>>> ind
array([[0, 1],
       [0, 1]])
>>> np.take_along_axis(x, ind, axis=1) # same as np.sort(x, axis=1)
array([[0, 3],
       [2, 2]])
```

Indices of the sorted elements of an N-dimensional array:

```
>>> ind = np.unravel_index(np.argsort(x, axis=None), x.shape)
>>> ind
(array([0, 1, 1, 0]), array([0, 0, 1, 1]))
>>> x[ind] # same as np.sort(x, axis=None)
array([0, 2, 2, 3])
```

Sorting with keys:

```
>>> x = np.array([(1, 0), (0, 1)], dtype=[('x', '<i4'), ('y', '<i4')])
>>> x
array([(1, 0), (0, 1)],
      dtype=[('x', '<i4'), ('y', '<i4')])
```

```
>>> np.argsort(x, order=('x', 'y'))
array([1, 0])
```

```
>>> np.argsort(x, order=('y', 'x'))
array([0, 1])
```

numpy.**sort_complex**(a)

Sort a complex array using the real part first, then the imaginary part.

Parameters

a
[array_like] Input array

Returns

out
[complex ndarray] Always returns a sorted complex array.

Examples

```
>>> import numpy as np
>>> np.sort_complex([5, 3, 6, 2, 1])
array([1.+0.j, 2.+0.j, 3.+0.j, 5.+0.j, 6.+0.j])
```

```
>>> np.sort_complex([1 + 2j, 2 - 1j, 3 - 2j, 3 - 3j, 3 + 5j])
array([1.+2.j, 2.-1.j, 3.-3.j, 3.-2.j, 3.+5.j])
```

`numpy.partition` (*a*, *kth*, *axis=-1*, *kind='introselect'*, *order=None*)

Return a partitioned copy of an array.

Creates a copy of the array and partially sorts it in such a way that the value of the element in *k*-th position is in the position it would be in a sorted array. In the output array, all elements smaller than the *k*-th element are located to the left of this element and all equal or greater are located to its right. The ordering of the elements in the two partitions on the either side of the *k*-th element in the output array is undefined.

Parameters

a

[array_like] Array to be sorted.

kth

[int or sequence of ints] Element index to partition by. The *k*-th value of the element will be in its final sorted position and all smaller elements will be moved before it and all equal or greater elements behind it. The order of all elements in the partitions is undefined. If provided with a sequence of *k*-th it will partition all elements indexed by *k*-th of them into their sorted position at once.

axis

[int or None, optional] Axis along which to sort. If None, the array is flattened before sorting. The default is -1, which sorts along the last axis.

kind

[{'introselect'}, optional] Selection algorithm. Default is 'introselect'.

order

[str or list of str, optional] When *a* is an array with fields defined, this argument specifies which fields to compare first, second, etc. A single field can be specified as a string. Not all fields need be specified, but unspecified fields will still be used, in the order in which they come up in the dtype, to break ties.

Returns

partitioned_array

[ndarray] Array of the same type and shape as *a*.

See also:

[*ndarray.partition*](#)

Method to sort an array in-place.

[*argsort*](#)

Indirect partition.

[*sort*](#)

Full sorting

Notes

The various selection algorithms are characterized by their average speed, worst case performance, work space size, and whether they are stable. A stable sort keeps items with the same key in the same relative order. The available algorithms have the following properties:

kind	speed	worst case	work space	stable
'introselect'	1	O(n)	0	no

All the partition algorithms make temporary copies of the data when partitioning along any but the last axis. Consequently, partitioning along the last axis is faster and uses less space than partitioning along any other axis.

The sort order for complex numbers is lexicographic. If both the real and imaginary parts are non-nan then the order is determined by the real parts except when they are equal, in which case the order is determined by the imaginary parts.

The sort order of `np.nan` is bigger than `np.inf`.

Examples

```
>>> import numpy as np
>>> a = np.array([7, 1, 7, 7, 1, 5, 7, 2, 3, 2, 6, 2, 3, 0])
>>> p = np.partition(a, 4)
>>> p
array([0, 1, 2, 1, 2, 5, 2, 3, 3, 6, 7, 7, 7, 7]) # may vary
```

`p[4]` is 2; all elements in `p[:4]` are less than or equal to `p[4]`, and all elements in `p[5:]` are greater than or equal to `p[4]`. The partition is:

```
[0, 1, 2, 1], [2], [5, 2, 3, 3, 6, 7, 7, 7, 7]
```

The next example shows the use of multiple values passed to *kth*.

```
>>> p2 = np.partition(a, (4, 8))
>>> p2
array([0, 1, 2, 1, 2, 3, 3, 2, 5, 6, 7, 7, 7, 7])
```

`p2[4]` is 2 and `p2[8]` is 5. All elements in `p2[:4]` are less than or equal to `p2[4]`, all elements in `p2[5:8]` are greater than or equal to `p2[4]` and less than or equal to `p2[8]`, and all elements in `p2[9:]` are greater than or equal to `p2[8]`. The partition is:

```
[0, 1, 2, 1], [2], [3, 3, 2], [5], [6, 7, 7, 7, 7]
```

`numpy.argpartition(a, kth, axis=-1, kind='introselect', order=None)`

Perform an indirect partition along the given axis using the algorithm specified by the *kind* keyword. It returns an array of indices of the same shape as *a* that index data along the given axis in partitioned order.

Parameters

a
[array_like] Array to sort.

kth
[int or sequence of ints] Element index to partition by. The k-th element will be in its final sorted position and all smaller elements will be moved before it and all larger elements behind

it. The order of all elements in the partitions is undefined. If provided with a sequence of k -th it will partition all of them into their sorted position at once.

axis

[int or None, optional] Axis along which to sort. The default is -1 (the last axis). If None, the flattened array is used.

kind

[{'introsort'}, optional] Selection algorithm. Default is 'introsort'

order

[str or list of str, optional] When a is an array with fields defined, this argument specifies which fields to compare first, second, etc. A single field can be specified as a string, and not all fields need be specified, but unspecified fields will still be used, in the order in which they come up in the dtype, to break ties.

Returns**index_array**

[ndarray, int] Array of indices that partition a along the specified axis. If a is one-dimensional, $a[\text{index_array}]$ yields a partitioned a . More generally, `np.take_along_axis(a, index_array, axis=axis)` always yields the partitioned a , irrespective of dimensionality.

See also:***partition***

Describes partition algorithms used.

ndarray.partition

Inplace partition.

argsort

Full indirect sort.

take_along_axis

Apply `index_array` from `argsort` to an array as if by calling `partition`.

Notes

The returned indices are not guaranteed to be sorted according to the values. Furthermore, the default selection algorithm `introsort` is unstable, and hence the returned indices are not guaranteed to be the earliest/latest occurrence of the element.

`argsort` works for real/complex inputs with nan values, see `partition` for notes on the enhanced sort order and different selection algorithms.

Examples

One dimensional array:

```
>>> import numpy as np
>>> x = np.array([3, 4, 2, 1])
>>> x[np.argsort(x, 3)]
array([2, 1, 3, 4]) # may vary
>>> x[np.argsort(x, (1, 3))]
array([1, 2, 3, 4]) # may vary
```

```
>>> x = [3, 4, 2, 1]
>>> np.array(x)[np.argpartition(x, 3)]
array([2, 1, 3, 4]) # may vary
```

Multi-dimensional array:

```
>>> x = np.array([[3, 4, 2], [1, 3, 1]])
>>> index_array = np.argpartition(x, kth=1, axis=-1)
>>> # below is the same as np.partition(x, kth=1)
>>> np.take_along_axis(x, index_array, axis=-1)
array([[2, 3, 4],
       [1, 1, 3]])
```

Searching

<code>argmax(a[, axis, out, keepdims])</code>	Returns the indices of the maximum values along an axis.
<code>nanargmax(a[, axis, out, keepdims])</code>	Return the indices of the maximum values in the specified axis ignoring NaNs.
<code>argmin(a[, axis, out, keepdims])</code>	Returns the indices of the minimum values along an axis.
<code>nanargmin(a[, axis, out, keepdims])</code>	Return the indices of the minimum values in the specified axis ignoring NaNs.
<code>argwhere(a)</code>	Find the indices of array elements that are non-zero, grouped by element.
<code>nonzero(a)</code>	Return the indices of the elements that are non-zero.
<code>flatnonzero(a)</code>	Return indices that are non-zero in the flattened version of a.
<code>where(condition, [x, y], /)</code>	Return elements chosen from <i>x</i> or <i>y</i> depending on <i>condition</i> .
<code>searchsorted(a, v[, side, sorter])</code>	Find indices where elements should be inserted to maintain order.
<code>extract(condition, arr)</code>	Return the elements of an array that satisfy some condition.

`numpy.argmax(a, axis=None, out=None, *, keepdims=<no value>)`

Returns the indices of the maximum values along an axis.

Parameters

a

[array_like] Input array.

axis

[int, optional] By default, the index is into the flattened array, otherwise along the specified axis.

out

[array, optional] If provided, the result will be inserted into this array. It should be of the appropriate shape and dtype.

keepdims

[bool, optional] If this is set to True, the axes which are reduced are left in the result as dimensions with size one. With this option, the result will broadcast correctly against the array.

New in version 1.22.0.

Returns

`index_array`

[ndarray of ints] Array of indices into the array. It has the same shape as `a.shape` with the dimension along *axis* removed. If *keepdims* is set to True, then the size of *axis* will be 1 with the resulting array having same shape as `a.shape`.

See also:

`ndarray.argmax`, `argmin`
`amax`

The maximum value along a given axis.

`unravel_index`

Convert a flat index into an index tuple.

`take_along_axis`

Apply `np.expand_dims(index_array, axis)` from `argmax` to an array as if by calling `max`.

Notes

In case of multiple occurrences of the maximum values, the indices corresponding to the first occurrence are returned.

Examples

```
>>> import numpy as np
>>> a = np.arange(6).reshape(2,3) + 10
>>> a
array([[10, 11, 12],
       [13, 14, 15]])
>>> np.argmax(a)
5
>>> np.argmax(a, axis=0)
array([1, 1, 1])
>>> np.argmax(a, axis=1)
array([2, 2])
```

Indexes of the maximal elements of an N-dimensional array:

```
>>> a.flat[np.argmax(a)]
15
>>> ind = np.unravel_index(np.argmax(a, axis=None), a.shape)
>>> ind
(1, 2)
>>> a[ind]
15
```

```
>>> b = np.arange(6)
>>> b[1] = 5
>>> b
array([0, 5, 2, 3, 4, 5])
>>> np.argmax(b) # Only the first occurrence is returned.
1
```

```

>>> x = np.array([[4,2,3], [1,0,3]])
>>> index_array = np.argmax(x, axis=-1)
>>> # Same as np.amax(x, axis=-1, keepdims=True)
>>> np.take_along_axis(x, np.expand_dims(index_array, axis=-1), axis=-1)
array([[4],
       [3]])
>>> # Same as np.amax(x, axis=-1)
>>> np.take_along_axis(x, np.expand_dims(index_array, axis=-1),
...     axis=-1).squeeze(axis=-1)
array([4, 3])

```

Setting *keepdims* to *True*,

```

>>> x = np.arange(24).reshape((2, 3, 4))
>>> res = np.argmax(x, axis=1, keepdims=True)
>>> res.shape
(2, 1, 4)

```

`numpy.nanargmax(a, axis=None, out=None, *, keepdims=<no value>)`

Return the indices of the maximum values in the specified axis ignoring NaNs. For all-NaN slices `ValueError` is raised. Warning: the results cannot be trusted if a slice contains only NaNs and -Infs.

Parameters

a

[array_like] Input data.

axis

[int, optional] Axis along which to operate. By default flattened input is used.

out

[array, optional] If provided, the result will be inserted into this array. It should be of the appropriate shape and dtype.

New in version 1.22.0.

keepdims

[bool, optional] If this is set to `True`, the axes which are reduced are left in the result as dimensions with size one. With this option, the result will broadcast correctly against the array.

New in version 1.22.0.

Returns

index_array

[ndarray] An array of indices or a single index value.

See also:

[*argmax*](#), [*nanargmin*](#)

Examples

```
>>> import numpy as np
>>> a = np.array([[np.nan, 4], [2, 3]])
>>> np.argmax(a)
0
>>> np.nanargmax(a)
1
>>> np.nanargmax(a, axis=0)
array([1, 0])
>>> np.nanargmax(a, axis=1)
array([1, 1])
```

`numpy.argmax(a, axis=None, out=None, *, keepdims=<no value>)`

Returns the indices of the minimum values along an axis.

Parameters

a

[array_like] Input array.

axis

[int, optional] By default, the index is into the flattened array, otherwise along the specified axis.

out

[array, optional] If provided, the result will be inserted into this array. It should be of the appropriate shape and dtype.

keepdims

[bool, optional] If this is set to True, the axes which are reduced are left in the result as dimensions with size one. With this option, the result will broadcast correctly against the array.

New in version 1.22.0.

Returns

index_array

[ndarray of ints] Array of indices into the array. It has the same shape as *a.shape* with the dimension along *axis* removed. If *keepdims* is set to True, then the size of *axis* will be 1 with the resulting array having same shape as *a.shape*.

See also:

[`ndarray.argmin, argmax`](#)

[`amin`](#)

The minimum value along a given axis.

[`unravel\_index`](#)

Convert a flat index into an index tuple.

[`take\_along\_axis`](#)

Apply `np.expand_dims(index_array, axis)` from `argmin` to an array as if by calling `min`.

Notes

In case of multiple occurrences of the minimum values, the indices corresponding to the first occurrence are returned.

Examples

```
>>> import numpy as np
>>> a = np.arange(6).reshape(2,3) + 10
>>> a
array([[10, 11, 12],
       [13, 14, 15]])
>>> np.argmin(a)
0
>>> np.argmin(a, axis=0)
array([0, 0, 0])
>>> np.argmin(a, axis=1)
array([0, 0])
```

Indices of the minimum elements of an N-dimensional array:

```
>>> a.flat[np.argmin(a)]
10
>>> ind = np.unravel_index(np.argmin(a, axis=None), a.shape)
>>> ind
(0, 0)
>>> a[ind]
10
```

```
>>> b = np.arange(6) + 10
>>> b[4] = 10
>>> b
array([10, 11, 12, 13, 10, 15])
>>> np.argmin(b)  # Only the first occurrence is returned.
0
```

```
>>> x = np.array([[4,2,3], [1,0,3]])
>>> index_array = np.argmin(x, axis=-1)
>>> # Same as np.amin(x, axis=-1, keepdims=True)
>>> np.take_along_axis(x, np.expand_dims(index_array, axis=-1), axis=-1)
array([[2],
       [0]])
>>> # Same as np.amax(x, axis=-1)
>>> np.take_along_axis(x, np.expand_dims(index_array, axis=-1),
...     axis=-1).squeeze(axis=-1)
array([2, 0])
```

Setting *keepdims* to *True*,

```
>>> x = np.arange(24).reshape((2, 3, 4))
>>> res = np.argmin(x, axis=1, keepdims=True)
>>> res.shape
(2, 1, 4)
```

`numpy.nanargmin(a, axis=None, out=None, *, keepdims=<no value>)`

Return the indices of the minimum values in the specified axis ignoring NaNs. For all-NaN slices `ValueError` is raised. Warning: the results cannot be trusted if a slice contains only NaNs and Infs.

Parameters**a**

[array_like] Input data.

axis

[int, optional] Axis along which to operate. By default flattened input is used.

out

[array, optional] If provided, the result will be inserted into this array. It should be of the appropriate shape and dtype.

New in version 1.22.0.

keepdims

[bool, optional] If this is set to True, the axes which are reduced are left in the result as dimensions with size one. With this option, the result will broadcast correctly against the array.

New in version 1.22.0.

Returns**index_array**

[ndarray] An array of indices or a single index value.

See also:

[*argmin*](#), [*nanargmax*](#)

Examples

```
>>> import numpy as np
>>> a = np.array([[np.nan, 4], [2, 3]])
>>> np.argmin(a)
0
>>> np.nanargmin(a)
2
>>> np.nanargmin(a, axis=0)
array([1, 1])
>>> np.nanargmin(a, axis=1)
array([1, 0])
```

`numpy.argwhere(a)`

Find the indices of array elements that are non-zero, grouped by element.

Parameters**a**

[array_like] Input data.

Returns**index_array**

[(N, a.ndim) ndarray] Indices of elements that are non-zero. Indices are grouped by element. This array will have shape (N, a.ndim) where N is the number of non-zero items.

See also:

where, nonzero

Notes

`np.argwhere(a)` is almost the same as `np.transpose(np.nonzero(a))`, but produces a result of the correct shape for a 0D array.

The output of `argwhere` is not suitable for indexing arrays. For this purpose use `nonzero(a)` instead.

Examples

```
>>> import numpy as np
>>> x = np.arange(6).reshape(2,3)
>>> x
array([[0, 1, 2],
       [3, 4, 5]])
>>> np.argwhere(x>1)
array([[0, 2],
       [1, 0],
       [1, 1],
       [1, 2]])
```

`numpy.flatnonzero(a)`

Return indices that are non-zero in the flattened version of `a`.

This is equivalent to `np.nonzero(np.ravel(a))[0]`.

Parameters

a
[array_like] Input data.

Returns

res
[ndarray] Output array, containing the indices of the elements of `a.ravel()` that are non-zero.

See also:

nonzero

Return the indices of the non-zero elements of the input array.

ravel

Return a 1-D array containing the elements of the input array.

Examples

```
>>> import numpy as np
>>> x = np.arange(-2, 3)
>>> x
array([-2, -1,  0,  1,  2])
>>> np.flatnonzero(x)
array([0, 1, 3, 4])
```

Use the indices of the non-zero elements as an index array to extract these elements:

```
>>> x.ravel()[np.flatnonzero(x)]  
array([-2, -1,  1,  2])
```

`numpy.searchsorted(a, v, side='left', sorter=None)`

Find indices where elements should be inserted to maintain order.

Find the indices into a sorted array *a* such that, if the corresponding elements in *v* were inserted before the indices, the order of *a* would be preserved.

Assuming that *a* is sorted:

<i>side</i>	returned index <i>i</i> satisfies
left	$a[i-1] < v \leq a[i]$
right	$a[i-1] \leq v < a[i]$

Parameters

a

[1-D array_like] Input array. If *sorter* is None, then it must be sorted in ascending order, otherwise *sorter* must be an array of indices that sort it.

v

[array_like] Values to insert into *a*.

side

[{'left', 'right'}, optional] If 'left', the index of the first suitable location found is given. If 'right', return the last such index. If there is no suitable index, return either 0 or N (where N is the length of *a*).

sorter

[1-D array_like, optional] Optional array of integer indices that sort array *a* into ascending order. They are typically the result of `argsort`.

Returns

indices

[int or array of ints] Array of insertion points with the same shape as *v*, or an integer if *v* is a scalar.

See also:

sort

Return a sorted copy of an array.

histogram

Produce histogram from 1-D data.

Notes

Binary search is used to find the required insertion points.

As of NumPy 1.4.0 *searchsorted* works with real/complex arrays containing *nan* values. The enhanced sort order is documented in *sort*.

This function uses the same algorithm as the builtin python `bisect.bisect_left` (`side='left'`) and `bisect.bisect_right` (`side='right'`) functions, which is also vectorized in the `v` argument.

Examples

```
>>> import numpy as np
>>> np.searchsorted([11,12,13,14,15], 13)
2
>>> np.searchsorted([11,12,13,14,15], 13, side='right')
3
>>> np.searchsorted([11,12,13,14,15], [-10, 20, 12, 13])
array([0, 5, 1, 2])
```

When *sorter* is used, the returned indices refer to the sorted array of *a* and not *a* itself:

```
>>> a = np.array([40, 10, 20, 30])
>>> sorter = np.argsort(a)
>>> sorter
array([1, 2, 3, 0]) # Indices that would sort the array 'a'
>>> result = np.searchsorted(a, 25, sorter=sorter)
>>> result
2
>>> a[sorter[result]]
30 # The element at index 2 of the sorted array is 30.
```

`numpy.extract` (*condition*, *arr*)

Return the elements of an array that satisfy some condition.

This is equivalent to `np.compress(ravel(condition), ravel(arr))`. If *condition* is boolean `np.extract` is equivalent to `arr[condition]`.

Note that *place* does the exact opposite of *extract*.

Parameters

condition

[array_like] An array whose nonzero or True entries indicate the elements of *arr* to extract.

arr

[array_like] Input array of the same size as *condition*.

Returns

extract

[ndarray] Rank 1 array of values from *arr* where *condition* is True.

See also:

take, *put*, *copyto*, *compress*, *place*

Examples

```
>>> import numpy as np
>>> arr = np.arange(12).reshape((3, 4))
>>> arr
array([[ 0,  1,  2,  3],
       [ 4,  5,  6,  7],
       [ 8,  9, 10, 11]])
>>> condition = np.mod(arr, 3)==0
>>> condition
array([[ True, False, False,  True],
       [False, False,  True, False],
       [False,  True, False, False]])
>>> np.extract(condition, arr)
array([0, 3, 6, 9])
```

If *condition* is boolean:

```
>>> arr[condition]
array([0, 3, 6, 9])
```

Counting

<code>count_nonzero(a[, axis, keepdims])</code>

Counts the number of non-zero values in the array *a*.

`numpy.count_nonzero(a, axis=None, *, keepdims=False)`

Counts the number of non-zero values in the array *a*.

A non-zero value is one that evaluates to truthful in a boolean context, including any non-zero number and any string that is not empty. This function recursively counts how many elements in *a* (and its sub-arrays) are non-zero values.

Parameters

a
[array_like] The array for which to count non-zeros.

axis
[int or tuple, optional] Axis or tuple of axes along which to count non-zeros. Default is None, meaning that non-zeros will be counted along a flattened version of *a*.

keepdims
[bool, optional] If this is set to True, the axes that are counted are left in the result as dimensions with size one. With this option, the result will broadcast correctly against the input array.

Returns

count
[int or array of int] Number of non-zero values in the array along a given axis. Otherwise, the total number of non-zero values in the array is returned.

See also:

nonzero

Return the coordinates of all the non-zero values.

Examples

```
>>> import numpy as np
>>> np.count_nonzero(np.eye(4))
np.int64(4)
>>> a = np.array([[0, 1, 7, 0],
...               [3, 0, 2, 19]])
>>> np.count_nonzero(a)
np.int64(5)
>>> np.count_nonzero(a, axis=0)
array([1, 1, 2, 1])
>>> np.count_nonzero(a, axis=1)
array([2, 3])
>>> np.count_nonzero(a, axis=1, keepdims=True)
array([[2],
       [3]])
```

1.4.17 Statistics

Order statistics

<code>ptp(a[, axis, out, keepdims])</code>	Range of values (maximum - minimum) along an axis.
<code>percentile(a, q[, axis, out, ...])</code>	Compute the q-th percentile of the data along the specified axis.
<code>nanpercentile(a, q[, axis, out, ...])</code>	Compute the qth percentile of the data along the specified axis, while ignoring nan values.
<code>quantile(a, q[, axis, out, overwrite_input, ...])</code>	Compute the q-th quantile of the data along the specified axis.
<code>nanquantile(a, q[, axis, out, ...])</code>	Compute the qth quantile of the data along the specified axis, while ignoring nan values.

`numpy.ptp(a, axis=None, out=None, keepdims=<no value>)`

Range of values (maximum - minimum) along an axis.

The name of the function comes from the acronym for ‘peak to peak’.

Warning: `ptp` preserves the data type of the array. This means the return value for an input of signed integers with n bits (e.g. `numpy.int8`, `numpy.int16`, etc) is also a signed integer with n bits. In that case, peak-to-peak values greater than $2^{n-1} - 1$ will be returned as negative values. An example with a work-around is shown below.

Parameters

a
[array_like] Input values.

axis
[None or int or tuple of ints, optional] Axis along which to find the peaks. By default, flatten the array. *axis* may be negative, in which case it counts from the last to the first axis. If this is a tuple of ints, a reduction is performed on multiple axes, instead of a single axis or all the axes as before.

out

[array_like] Alternative output array in which to place the result. It must have the same shape and buffer length as the expected output, but the type of the output values will be cast if necessary.

keepdims

[bool, optional] If this is set to True, the axes which are reduced are left in the result as dimensions with size one. With this option, the result will broadcast correctly against the input array.

If the default value is passed, then *keepdims* will not be passed through to the *ptp* method of sub-classes of *ndarray*, however any non-default value will be. If the sub-class' method does not implement *keepdims* any exceptions will be raised.

Returns**ptp**

[ndarray or scalar] The range of a given array - *scalar* if array is one-dimensional or a new array holding the result along the given axis

Examples

```
>>> import numpy as np
>>> x = np.array([[4, 9, 2, 10],
...               [6, 9, 7, 12]])
```

```
>>> np.ptp(x, axis=1)
array([8, 6])
```

```
>>> np.ptp(x, axis=0)
array([2, 0, 5, 2])
```

```
>>> np.ptp(x)
10
```

This example shows that a negative value can be returned when the input is an array of signed integers.

```
>>> y = np.array([[1, 127],
...               [0, 127],
...               [-1, 127],
...               [-2, 127]], dtype=np.int8)
>>> np.ptp(y, axis=1)
array([ 126, 127, -128, -127], dtype=int8)
```

A work-around is to use the *view()* method to view the result as unsigned integers with the same bit width:

```
>>> np.ptp(y, axis=1).view(np.uint8)
array([126, 127, 128, 129], dtype=uint8)
```

`numpy.percentile` (*a*, *q*, *axis=None*, *out=None*, *overwrite_input=False*, *method='linear'*, *keepdims=False*, *, *weights=None*)

Compute the *q*-th percentile of the data along the specified axis.

Returns the *q*-th percentile(s) of the array elements.

Parameters

a

[array_like of real numbers] Input array or object that can be converted to an array.

q

[array_like of float] Percentage or sequence of percentages for the percentiles to compute. Values must be between 0 and 100 inclusive.

axis

[{int, tuple of int, None}, optional] Axis or axes along which the percentiles are computed. The default is to compute the percentile(s) along a flattened version of the array.

out

[ndarray, optional] Alternative output array in which to place the result. It must have the same shape and buffer length as the expected output, but the type (of the output) will be cast if necessary.

overwrite_input[bool, optional] If True, then allow the input array *a* to be modified by intermediate calculations, to save memory. In this case, the contents of the input *a* after this function completes is undefined.**method**

[str, optional] This parameter specifies the method to use for estimating the percentile. There are many different methods, some unique to NumPy. See the notes for explanation. The options sorted by their R type as summarized in the H&F paper [1] are:

1. 'inverted_cdf'
2. 'averaged_inverted_cdf'
3. 'closest_observation'
4. 'interpolated_inverted_cdf'
5. 'hazen'
6. 'weibull'
7. 'linear' (default)
8. 'median_unbiased'
9. 'normal_unbiased'

The first three methods are discontinuous. NumPy further defines the following discontinuous variations of the default 'linear' (7.) option:

- 'lower'
- 'higher',
- 'midpoint'
- 'nearest'

Changed in version 1.22.0: This argument was previously called "interpolation" and only offered the "linear" default and last four options.

keepdims[bool, optional] If this is set to True, the axes which are reduced are left in the result as dimensions with size one. With this option, the result will broadcast correctly against the original array *a*.**weights**[array_like, optional] An array of weights associated with the values in *a*. Each value in *a*

contributes to the percentile according to its associated weight. The weights array can either be 1-D (in which case its length must be the size of *a* along the given axis) or of the same shape as *a*. If *weights=None*, then all data in *a* are assumed to have a weight equal to one. Only *method="inverted_cdf"* supports weights. See the notes for more details.

New in version 2.0.0.

Returns

percentile

[scalar or ndarray] If *q* is a single percentile and *axis=None*, then the result is a scalar. If multiple percentiles are given, first axis of the result corresponds to the percentiles. The other axes are the axes that remain after the reduction of *a*. If the input contains integers or floats smaller than `float64`, the output data-type is `float64`. Otherwise, the output data-type is the same as that of the input. If *out* is specified, that array is returned instead.

See also:

mean

median

equivalent to `percentile(..., 50)`

nanpercentile

quantile

equivalent to `percentile`, except *q* in the range [0, 1].

Notes

The behavior of `numpy.percentile` with percentage *q* is that of `numpy.quantile` with argument *q*/100. For more information, please see `numpy.quantile`.

References

[1]

Examples

```
>>> import numpy as np
>>> a = np.array([[10, 7, 4], [3, 2, 1]])
>>> a
array([[10,  7,  4],
       [ 3,  2,  1]])
>>> np.percentile(a, 50)
3.5
>>> np.percentile(a, 50, axis=0)
array([6.5, 4.5, 2.5])
>>> np.percentile(a, 50, axis=1)
array([7.,  2.])
>>> np.percentile(a, 50, axis=1, keepdims=True)
array([[7.],
       [2.]])
```

```
>>> m = np.percentile(a, 50, axis=0)
>>> out = np.zeros_like(m)
>>> np.percentile(a, 50, axis=0, out=out)
array([6.5, 4.5, 2.5])
>>> m
array([6.5, 4.5, 2.5])
```

```
>>> b = a.copy()
>>> np.percentile(b, 50, axis=1, overwrite_input=True)
array([7., 2.])
>>> assert not np.all(a == b)
```

The different methods can be visualized graphically:

```
import matplotlib.pyplot as plt

a = np.arange(4)
p = np.linspace(0, 100, 6001)
ax = plt.gca()
lines = [
    ('linear', '-', 'C0'),
    ('inverted_cdf', ':', 'C1'),
    # Almost the same as `inverted_cdf`:
    ('averaged_inverted_cdf', '-.', 'C1'),
    ('closest_observation', ':', 'C2'),
    ('interpolated_inverted_cdf', '--', 'C1'),
    ('hazen', '--', 'C3'),
    ('weibull', '-.', 'C4'),
    ('median_unbiased', '--', 'C5'),
    ('normal_unbiased', '-.', 'C6'),
]
for method, style, color in lines:
    ax.plot(
        p, np.percentile(a, p, method=method),
        label=method, linestyle=style, color=color)
ax.set(
    title='Percentiles for different methods and data: ' + str(a),
    xlabel='Percentile',
    ylabel='Estimated percentile value',
    yticks=a)
ax.legend(bbox_to_anchor=(1.03, 1))
plt.tight_layout()
plt.show()
```

`numpy.nanpercentile(a, q, axis=None, out=None, overwrite_input=False, method='linear', keepdims=<no value>, *, weights=None)`

Compute the qth percentile of the data along the specified axis, while ignoring nan values.

Returns the qth percentile(s) of the array elements.

Parameters

a

[array_like] Input array or object that can be converted to an array, containing nan values to be ignored.

q

[array_like of float] Percentile or sequence of percentiles to compute, which must be between

Percentiles for different methods and data: [0 1 2 3]

0 and 100 inclusive.

axis

[{int, tuple of int, None}, optional] Axis or axes along which the percentiles are computed. The default is to compute the percentile(s) along a flattened version of the array.

out

[ndarray, optional] Alternative output array in which to place the result. It must have the same shape and buffer length as the expected output, but the type (of the output) will be cast if necessary.

overwrite_input

[bool, optional] If True, then allow the input array *a* to be modified by intermediate calculations, to save memory. In this case, the contents of the input *a* after this function completes is undefined.

method

[str, optional] This parameter specifies the method to use for estimating the percentile. There are many different methods, some unique to NumPy. See the notes for explanation. The options sorted by their R type as summarized in the H&F paper [1] are:

1. 'inverted_cdf'
2. 'averaged_inverted_cdf'
3. 'closest_observation'
4. 'interpolated_inverted_cdf'
5. 'hazen'
6. 'weibull'
7. 'linear' (default)
8. 'median_unbiased'
9. 'normal_unbiased'

The first three methods are discontinuous. NumPy further defines the following discontinuous variations of the default 'linear' (7.) option:

- ‘lower’
- ‘higher’,
- ‘midpoint’
- ‘nearest’

Changed in version 1.22.0: This argument was previously called “interpolation” and only offered the “linear” default and last four options.

keepdims

[bool, optional] If this is set to True, the axes which are reduced are left in the result as dimensions with size one. With this option, the result will broadcast correctly against the original array *a*.

If this is anything but the default value it will be passed through (in the special case of an empty array) to the `mean` function of the underlying array. If the array is a sub-class and `mean` does not have the kwarg `keepdims` this will raise a `RuntimeError`.

weights

[array_like, optional] An array of weights associated with the values in *a*. Each value in *a* contributes to the percentile according to its associated weight. The weights array can either be 1-D (in which case its length must be the size of *a* along the given axis) or of the same shape as *a*. If `weights=None`, then all data in *a* are assumed to have a weight equal to one. Only `method="inverted_cdf"` supports weights.

New in version 2.0.0.

Returns

percentile

[scalar or ndarray] If *q* is a single percentile and `axis=None`, then the result is a scalar. If multiple percentiles are given, first axis of the result corresponds to the percentiles. The other axes are the axes that remain after the reduction of *a*. If the input contains integers or floats smaller than `float64`, the output data-type is `float64`. Otherwise, the output data-type is the same as that of the input. If *out* is specified, that array is returned instead.

See also:

`nanmean`

`nanmedian`

equivalent to `nanpercentile(..., 50)`

`percentile`, `median`, `mean`

`nanquantile`

equivalent to `nanpercentile`, except *q* in range [0, 1].

Notes

The behavior of `numpy.nanpercentile` with percentage *q* is that of `numpy.quantile` with argument *q*/100 (ignoring nan values). For more information, please see `numpy.quantile`.

Examples

```
>>> import numpy as np
>>> a = np.array([[10., 7., 4.], [3., 2., 1.]])
>>> a[0][1] = np.nan
>>> a
array([[10., nan, 4.],
       [ 3.,  2., 1.]])
>>> np.percentile(a, 50)
np.float64(nan)
>>> np.nanpercentile(a, 50)
3.0
>>> np.nanpercentile(a, 50, axis=0)
array([6.5, 2. , 2.5])
>>> np.nanpercentile(a, 50, axis=1, keepdims=True)
array([[7.],
       [2.]])
>>> m = np.nanpercentile(a, 50, axis=0)
>>> out = np.zeros_like(m)
>>> np.nanpercentile(a, 50, axis=0, out=out)
array([6.5, 2. , 2.5])
>>> m
array([6.5, 2. , 2.5])
```

```
>>> b = a.copy()
>>> np.nanpercentile(b, 50, axis=1, overwrite_input=True)
array([7., 2.])
>>> assert not np.all(a==b)
```

`numpy.quantile(a, q, axis=None, out=None, overwrite_input=False, method='linear', keepdims=False, *, weights=None)`

Compute the q-th quantile of the data along the specified axis.

Parameters

a

[array_like of real numbers] Input array or object that can be converted to an array.

q

[array_like of float] Probability or sequence of probabilities of the quantiles to compute. Values must be between 0 and 1 inclusive.

axis

[{int, tuple of int, None}, optional] Axis or axes along which the quantiles are computed. The default is to compute the quantile(s) along a flattened version of the array.

out

[ndarray, optional] Alternative output array in which to place the result. It must have the same shape and buffer length as the expected output, but the type (of the output) will be cast if necessary.

overwrite_input

[bool, optional] If True, then allow the input array *a* to be modified by intermediate calcula-

tions, to save memory. In this case, the contents of the input *a* after this function completes is undefined.

method

[str, optional] This parameter specifies the method to use for estimating the quantile. There are many different methods, some unique to NumPy. The recommended options, numbered as they appear in [1], are:

1. 'inverted_cdf'
2. 'averaged_inverted_cdf'
3. 'closest_observation'
4. 'interpolated_inverted_cdf'
5. 'hazen'
6. 'weibull'
7. 'linear' (default)
8. 'median_unbiased'
9. 'normal_unbiased'

The first three methods are discontinuous. For backward compatibility with previous versions of NumPy, the following discontinuous variations of the default 'linear' (7.) option are available:

- 'lower'
- 'higher',
- 'midpoint'
- 'nearest'

See Notes for details.

Changed in version 1.22.0: This argument was previously called “interpolation” and only offered the “linear” default and last four options.

keepdims

[bool, optional] If this is set to True, the axes which are reduced are left in the result as dimensions with size one. With this option, the result will broadcast correctly against the original array *a*.

weights

[array_like, optional] An array of weights associated with the values in *a*. Each value in *a* contributes to the quantile according to its associated weight. The weights array can either be 1-D (in which case its length must be the size of *a* along the given axis) or of the same shape as *a*. If *weights=None*, then all data in *a* are assumed to have a weight equal to one. Only *method="inverted_cdf"* supports weights. See the notes for more details.

New in version 2.0.0.

Returns

quantile

[scalar or ndarray] If *q* is a single probability and *axis=None*, then the result is a scalar. If multiple probability levels are given, first axis of the result corresponds to the quantiles. The other axes are the axes that remain after the reduction of *a*. If the input contains integers or floats smaller than `float64`, the output data-type is `float64`. Otherwise, the output data-type is the same as that of the input. If *out* is specified, that array is returned instead.

See also:

mean

percentile

equivalent to `quantile`, but with `q` in the range `[0, 100]`.

median

equivalent to `quantile(..., 0.5)`

nanquantile

Notes

Given a sample a from an underlying distribution, *quantile* provides a nonparametric estimate of the inverse cumulative distribution function.

By default, this is done by interpolating between adjacent elements in y , a sorted copy of a :

```
(1-g)*y[j] + g*y[j+1]
```

where the index j and coefficient g are the integral and fractional components of $q * (n-1)$, and n is the number of elements in the sample.

This is a special case of Equation 1 of H&F [1]. More generally,

- $j = (q*n + m - 1) // 1$, and
- $g = (q*n + m - 1) \% 1$,

where m may be defined according to several different conventions. The preferred convention may be selected using the `method` parameter:

method	number in H&F	m
<code>interpolated_inverted_cdf</code>	4	0
<code>hazen</code>	5	$1/2$
<code>weibull</code>	6	q
<code>linear (default)</code>	7	$1 - q$
<code>median_unbiased</code>	8	$q/3 + 1/3$
<code>normal_unbiased</code>	9	$q/4 + 3/8$

Note that indices j and $j + 1$ are clipped to the range 0 to $n - 1$ when the results of the formula would be outside the allowed range of non-negative indices. The $- 1$ in the formulas for j and g accounts for Python's 0-based indexing.

The table above includes only the estimators from H&F that are continuous functions of probability q (estimators 4-9). NumPy also provides the three discontinuous estimators from H&F (estimators 1-3), where j is defined as above, m is defined as follows, and g is a function of the real-valued $\text{index} = q*n + m - 1$ and j .

1. `inverted_cdf`: $m = 0$ and $g = \text{int}(\text{index} - j > 0)$
2. `averaged_inverted_cdf`: $m = 0$ and $g = (1 + \text{int}(\text{index} - j > 0)) / 2$
3. `closest_observation`: $m = -1/2$ and $g = 1 - \text{int}((\text{index} == j) \& (j\%2 == 1))$

For backward compatibility with previous versions of NumPy, *quantile* provides four additional discontinuous estimators. Like `method='linear'`, all have $m = 1 - q$ so that $j = q*(n-1) // 1$, but g is defined as follows.

- `lower`: $g = 0$

- midpoint: $g = 0.5$
- higher: $g = 1$
- nearest: $g = (q * (n-1) \% 1) > 0.5$

Weighted quantiles: More formally, the quantile at probability level q of a cumulative distribution function $F(y) = P(Y \leq y)$ with probability measure P is defined as any number x that fulfills the *coverage conditions*

$$P(Y < x) \leq q \quad \text{and} \quad P(Y \leq x) \geq q$$

with random variable $Y \sim P$. Sample quantiles, the result of `quantile`, provide nonparametric estimation of the underlying population counterparts, represented by the unknown F , given a data vector a of length n .

Some of the estimators above arise when one considers F as the empirical distribution function of the data, i.e. $F(y) = \frac{1}{n} \sum_i 1_{a_i \leq y}$. Then, different methods correspond to different choices of x that fulfill the above coverage conditions. Methods that follow this approach are `inverted_cdf` and `averaged_inverted_cdf`.

For weighted quantiles, the coverage conditions still hold. The empirical cumulative distribution is simply replaced by its weighted version, i.e. $P(Y \leq t) = \frac{1}{\sum_i w_i} \sum_i w_i 1_{x_i \leq t}$. Only `method="inverted_cdf"` supports weights.

Examples

```
>>> import numpy as np
>>> a = np.array([[10, 7, 4], [3, 2, 1]])
>>> a
array([[10,  7,  4],
       [ 3,  2,  1]])
>>> np.quantile(a, 0.5)
3.5
>>> np.quantile(a, 0.5, axis=0)
array([6.5, 4.5, 2.5])
>>> np.quantile(a, 0.5, axis=1)
array([7.,  2.])
>>> np.quantile(a, 0.5, axis=1, keepdims=True)
array([[7.],
       [2.]])
>>> m = np.quantile(a, 0.5, axis=0)
>>> out = np.zeros_like(m)
>>> np.quantile(a, 0.5, axis=0, out=out)
array([6.5, 4.5, 2.5])
>>> m
array([6.5, 4.5, 2.5])
>>> b = a.copy()
>>> np.quantile(b, 0.5, axis=1, overwrite_input=True)
array([7.,  2.])
>>> assert not np.all(a == b)
```

See also `numpy.percentile` for a visualization of most methods.

`numpy.nanquantile` (*a*, *q*, *axis=None*, *out=None*, *overwrite_input=False*, *method='linear'*, *keepdims=<no value>*,
*, *weights=None*)

Compute the qth quantile of the data along the specified axis, while ignoring nan values. Returns the qth quantile(s) of the array elements.

Parameters

a

[array_like] Input array or object that can be converted to an array, containing nan values to be ignored

q

[array_like of float] Probability or sequence of probabilities for the quantiles to compute. Values must be between 0 and 1 inclusive.

axis

[{int, tuple of int, None}, optional] Axis or axes along which the quantiles are computed. The default is to compute the quantile(s) along a flattened version of the array.

out

[ndarray, optional] Alternative output array in which to place the result. It must have the same shape and buffer length as the expected output, but the type (of the output) will be cast if necessary.

overwrite_input

[bool, optional] If True, then allow the input array *a* to be modified by intermediate calculations, to save memory. In this case, the contents of the input *a* after this function completes is undefined.

method

[str, optional] This parameter specifies the method to use for estimating the quantile. There are many different methods, some unique to NumPy. See the notes for explanation. The options sorted by their R type as summarized in the H&F paper [1] are:

1. 'inverted_cdf'
2. 'averaged_inverted_cdf'
3. 'closest_observation'
4. 'interpolated_inverted_cdf'
5. 'hazen'
6. 'weibull'
7. 'linear' (default)
8. 'median_unbiased'
9. 'normal_unbiased'

The first three methods are discontinuous. NumPy further defines the following discontinuous variations of the default 'linear' (7.) option:

- 'lower'
- 'higher',
- 'midpoint'
- 'nearest'

Changed in version 1.22.0: This argument was previously called "interpolation" and only offered the "linear" default and last four options.

keepdims

[bool, optional] If this is set to True, the axes which are reduced are left in the result as dimensions with size one. With this option, the result will broadcast correctly against the original array *a*.

If this is anything but the default value it will be passed through (in the special case of an empty array) to the `mean` function of the underlying array. If the array is a sub-class and `mean` does not have the kwarg `keepdims` this will raise a `RuntimeError`.

weights

[array_like, optional] An array of weights associated with the values in *a*. Each value in *a* contributes to the quantile according to its associated weight. The weights array can either be 1-D (in which case its length must be the size of *a* along the given axis) or of the same shape as *a*. If `weights=None`, then all data in *a* are assumed to have a weight equal to one. Only `method="inverted_cdf"` supports weights.

New in version 2.0.0.

Returns**quantile**

[scalar or ndarray] If *q* is a single probability and `axis=None`, then the result is a scalar. If multiple probability levels are given, first axis of the result corresponds to the quantiles. The other axes are the axes that remain after the reduction of *a*. If the input contains integers or floats smaller than `float64`, the output data-type is `float64`. Otherwise, the output data-type is the same as that of the input. If *out* is specified, that array is returned instead.

See also:

[`quantile`](#)

[`nanmean`](#), [`nanmedian`](#)

[`nanmedian`](#)

equivalent to `nanquantile(..., 0.5)`

[`nanpercentile`](#)

same as `nanquantile`, but with *q* in the range [0, 100].

Notes

The behavior of `numpy.nanquantile` is the same as that of `numpy.quantile` (ignoring nan values). For more information, please see [`numpy.quantile`](#).

Examples

```

>>> import numpy as np
>>> a = np.array([[10., 7., 4.], [3., 2., 1.]])
>>> a[0][1] = np.nan
>>> a
array([[10., nan, 4.],
       [ 3.,  2.,  1.]])
>>> np.quantile(a, 0.5)
np.float64(nan)
>>> np.nanquantile(a, 0.5)
3.0
>>> np.nanquantile(a, 0.5, axis=0)
array([6.5, 2. , 2.5])
>>> np.nanquantile(a, 0.5, axis=1, keepdims=True)
array([[7.],
       [2.]])
>>> m = np.nanquantile(a, 0.5, axis=0)
>>> out = np.zeros_like(m)
>>> np.nanquantile(a, 0.5, axis=0, out=out)
array([6.5, 2. , 2.5])
>>> m
array([6.5, 2. , 2.5])
>>> b = a.copy()
>>> np.nanquantile(b, 0.5, axis=1, overwrite_input=True)
array([7., 2.])
>>> assert not np.all(a==b)

```

Averages and variances

<code>median(a[, axis, out, overwrite_input, keepdims])</code>	Compute the median along the specified axis.
<code>average(a[, axis, weights, returned, keepdims])</code>	Compute the weighted average along the specified axis.
<code>mean(a[, axis, dtype, out, keepdims, where])</code>	Compute the arithmetic mean along the specified axis.
<code>std(a[, axis, dtype, out, ddof, keepdims, ...])</code>	Compute the standard deviation along the specified axis.
<code>var(a[, axis, dtype, out, ddof, keepdims, ...])</code>	Compute the variance along the specified axis.
<code>nanmedian(a[, axis, out, overwrite_input, ...])</code>	Compute the median along the specified axis, while ignoring NaNs.
<code>nanmean(a[, axis, dtype, out, keepdims, where])</code>	Compute the arithmetic mean along the specified axis, ignoring NaNs.
<code>nanstd(a[, axis, dtype, out, ddof, ...])</code>	Compute the standard deviation along the specified axis, while ignoring NaNs.
<code>nanvar(a[, axis, dtype, out, ddof, ...])</code>	Compute the variance along the specified axis, while ignoring NaNs.

`numpy.median(a, axis=None, out=None, overwrite_input=False, keepdims=False)`

Compute the median along the specified axis.

Returns the median of the array elements.

Parameters

a

[array_like] Input array or object that can be converted to an array.

axis

[{int, sequence of int, None}, optional] Axis or axes along which the medians are computed. The default, `axis=None`, will compute the median along a flattened version of the array. If a sequence of axes, the array is first flattened along the given axes, then the median is computed along the resulting flattened axis.

out

[ndarray, optional] Alternative output array in which to place the result. It must have the same shape and buffer length as the expected output, but the type (of the output) will be cast if necessary.

overwrite_input

[bool, optional] If True, then allow use of memory of input array *a* for calculations. The input array will be modified by the call to `median`. This will save memory when you do not need to preserve the contents of the input array. Treat the input as undefined, but it will probably be fully or partially sorted. Default is False. If `overwrite_input` is True and *a* is not already an `ndarray`, an error will be raised.

keepdims

[bool, optional] If this is set to True, the axes which are reduced are left in the result as dimensions with size one. With this option, the result will broadcast correctly against the original *arr*.

Returns**median**

[ndarray] A new array holding the result. If the input contains integers or floats smaller than `float64`, then the output data-type is `np.float64`. Otherwise, the data-type of the output is the same as that of the input. If *out* is specified, that array is returned instead.

See also:

[`mean`](#), [`percentile`](#)

Notes

Given a vector *V* of length *N*, the median of *V* is the middle value of a sorted copy of *V*, *V_sorted* - i.e., *V_sorted*[(*N*-1)/2], when *N* is odd, and the average of the two middle values of *V_sorted* when *N* is even.

Examples

```
>>> import numpy as np
>>> a = np.array([[10, 7, 4], [3, 2, 1]])
>>> a
array([[10,  7,  4],
       [ 3,  2,  1]])
>>> np.median(a)
np.float64(3.5)
>>> np.median(a, axis=0)
array([6.5, 4.5, 2.5])
>>> np.median(a, axis=1)
array([7.,  2.])
>>> np.median(a, axis=(0, 1))
np.float64(3.5)
```

(continues on next page)

(continued from previous page)

```

>>> m = np.median(a, axis=0)
>>> out = np.zeros_like(m)
>>> np.median(a, axis=0, out=m)
array([6.5,  4.5,  2.5])
>>> m
array([6.5,  4.5,  2.5])
>>> b = a.copy()
>>> np.median(b, axis=1, overwrite_input=True)
array([7.,  2.])
>>> assert not np.all(a==b)
>>> b = a.copy()
>>> np.median(b, axis=None, overwrite_input=True)
np.float64(3.5)
>>> assert not np.all(a==b)

```

`numpy.average` (*a*, *axis=None*, *weights=None*, *returned=False*, *, *keepdims=<no value>*)

Compute the weighted average along the specified axis.

Parameters

a

[array_like] Array containing data to be averaged. If *a* is not an array, a conversion is attempted.

axis

[None or int or tuple of ints, optional] Axis or axes along which to average *a*. The default, *axis=None*, will average over all of the elements of the input array. If *axis* is negative it counts from the last to the first axis. If *axis* is a tuple of ints, averaging is performed on all of the axes specified in the tuple instead of a single axis or all the axes as before.

weights

[array_like, optional] An array of weights associated with the values in *a*. Each value in *a* contributes to the average according to its associated weight. The array of weights must be the same shape as *a* if no axis is specified, otherwise the weights must have dimensions and shape consistent with *a* along the specified axis. If *weights=None*, then all data in *a* are assumed to have a weight equal to one. The calculation is:

```
avg = sum(a * weights) / sum(weights)
```

where the sum is over all included elements. The only constraint on the values of *weights* is that *sum(weights)* must not be 0.

returned

[bool, optional] Default is *False*. If *True*, the tuple (*average*, *sum_of_weights*) is returned, otherwise only the average is returned. If *weights=None*, *sum_of_weights* is equivalent to the number of elements over which the average is taken.

keepdims

[bool, optional] If this is set to *True*, the axes which are reduced are left in the result as dimensions with size one. With this option, the result will broadcast correctly against the original *a*. *Note: keepdims* will not work with instances of `numpy.matrix` or other classes whose methods do not support *keepdims*.

New in version 1.23.0.

Returns

retval, [sum_of_weights]

[array_type or double] Return the average along the specified axis. When *returned* is *True*,

return a tuple with the average as the first element and the sum of the weights as the second element. *sum_of_weights* is of the same type as *retval*. The result dtype follows a general pattern. If *weights* is None, the result dtype will be that of *a*, or `float64` if *a* is integral. Otherwise, if *weights* is not None and *a* is non-integral, the result type will be the type of lowest precision capable of representing values of both *a* and *weights*. If *a* happens to be integral, the previous rules still applies but the result dtype will at least be `float64`.

Raises

ZeroDivisionError

When all weights along axis are zero. See `numpy.ma.average` for a version robust to this type of error.

TypeError

When *weights* does not have the same shape as *a*, and *axis=None*.

ValueError

When *weights* does not have dimensions and shape consistent with *a* along specified *axis*.

See also:

`mean`

`ma.average`

average for masked arrays – useful if your data contains “missing” values

`numpy.result_type`

Returns the type that results from applying the numpy type promotion rules to the arguments.

Examples

```
>>> import numpy as np
>>> data = np.arange(1, 5)
>>> data
array([1, 2, 3, 4])
>>> np.average(data)
2.5
>>> np.average(np.arange(1, 11), weights=np.arange(10, 0, -1))
4.0
```

```
>>> data = np.arange(6).reshape((3, 2))
>>> data
array([[0, 1],
       [2, 3],
       [4, 5]])
>>> np.average(data, axis=1, weights=[1./4, 3./4])
array([0.75, 2.75, 4.75])
>>> np.average(data, weights=[1./4, 3./4])
Traceback (most recent call last):
...
TypeError: Axis must be specified when shapes of a and weights differ.
```

With `keepdims=True`, the following result has shape (3, 1).

```
>>> np.average(data, axis=1, keepdims=True)
array([[0.5],
       [2.5],
       [4.5]])
```

```

>>> data = np.arange(8).reshape((2, 2, 2))
>>> data
array([[[0, 1],
        [2, 3]],
       [[4, 5],
        [6, 7]]])
>>> np.average(data, axis=(0, 1), weights=[[1./4, 3./4], [1., 1./2]])
array([3.4, 4.4])
>>> np.average(data, axis=0, weights=[[1./4, 3./4], [1., 1./2]])
Traceback (most recent call last):
...
ValueError: Shape of weights must be consistent
with shape of a along specified axis.

```

`numpy.mean(a, axis=None, dtype=None, out=None, keepdims=<no value>, *, where=<no value>)`

Compute the arithmetic mean along the specified axis.

Returns the average of the array elements. The average is taken over the flattened array by default, otherwise over the specified axis. *float64* intermediate and return values are used for integer inputs.

Parameters

a

[array_like] Array containing numbers whose mean is desired. If *a* is not an array, a conversion is attempted.

axis

[None or int or tuple of ints, optional] Axis or axes along which the means are computed. The default is to compute the mean of the flattened array.

If this is a tuple of ints, a mean is performed over multiple axes, instead of a single axis or all the axes as before.

dtype

[data-type, optional] Type to use in computing the mean. For integer inputs, the default is *float64*; for floating point inputs, it is the same as the input dtype.

out

[ndarray, optional] Alternate output array in which to place the result. The default is *None*; if provided, it must have the same shape as the expected output, but the type will be cast if necessary. See *ufuncs-output-type* for more details. See *ufuncs-output-type* for more details.

keepdims

[bool, optional] If this is set to *True*, the axes which are reduced are left in the result as dimensions with size one. With this option, the result will broadcast correctly against the input array.

If the default value is passed, then *keepdims* will not be passed through to the *mean* method of sub-classes of *ndarray*, however any non-default value will be. If the sub-class' method does not implement *keepdims* any exceptions will be raised.

where

[array_like of bool, optional] Elements to include in the mean. See *reduce* for details.

New in version 1.20.0.

Returns

m

[ndarray, see dtype parameter above] If *out=None*, returns a new array containing the mean values, otherwise a reference to the output array is returned.

See also:

average

Weighted average

std, *var*, *nanmean*, *nanstd*, *nanvar*

Notes

The arithmetic mean is the sum of the elements along the axis divided by the number of elements.

Note that for floating-point input, the mean is computed using the same precision the input has. Depending on the input data, this can cause the results to be inaccurate, especially for *float32* (see example below). Specifying a higher-precision accumulator using the *dtype* keyword can alleviate this issue.

By default, *float16* results are computed using *float32* intermediates for extra precision.

Examples

```
>>> import numpy as np
>>> a = np.array([[1, 2], [3, 4]])
>>> np.mean(a)
2.5
>>> np.mean(a, axis=0)
array([2., 3.])
>>> np.mean(a, axis=1)
array([1.5, 3.5])
```

In single precision, *mean* can be inaccurate:

```
>>> a = np.zeros((2, 512*512), dtype=np.float32)
>>> a[0, :] = 1.0
>>> a[1, :] = 0.1
>>> np.mean(a)
np.float32(0.54999924)
```

Computing the mean in float64 is more accurate:

```
>>> np.mean(a, dtype=np.float64)
0.550000000074505806 # may vary
```

Computing the mean in timedelta64 is available:

```
>>> b = np.array([1, 3], dtype="timedelta64[D]")
>>> np.mean(b)
np.timedelta64(2, 'D')
```

Specifying a where argument:

```
>>> a = np.array([[5, 9, 13], [14, 10, 12], [11, 15, 19]])
>>> np.mean(a)
12.0
>>> np.mean(a, where=[[True], [False], [False]])
9.0
```

`numpy.std(a, axis=None, dtype=None, out=None, ddof=0, keepdims=<no value>, *, where=<no value>, mean=<no value>, correction=<no value>)`

Compute the standard deviation along the specified axis.

Returns the standard deviation, a measure of the spread of a distribution, of the array elements. The standard deviation is computed for the flattened array by default, otherwise over the specified axis.

Parameters

a

[array_like] Calculate the standard deviation of these values.

axis

[None or int or tuple of ints, optional] Axis or axes along which the standard deviation is computed. The default is to compute the standard deviation of the flattened array. If this is a tuple of ints, a standard deviation is performed over multiple axes, instead of a single axis or all the axes as before.

dtype

[dtype, optional] Type to use in computing the standard deviation. For arrays of integer type the default is float64, for arrays of float types it is the same as the array type.

out

[ndarray, optional] Alternative output array in which to place the result. It must have the same shape as the expected output but the type (of the calculated values) will be cast if necessary. See [ufuncs-output-type](#) for more details.

ddof

[[int, float], optional] Means Delta Degrees of Freedom. The divisor used in calculations is $N - \text{ddof}$, where N represents the number of elements. By default *ddof* is zero. See Notes for details about use of *ddof*.

keepdims

[bool, optional] If this is set to True, the axes which are reduced are left in the result as dimensions with size one. With this option, the result will broadcast correctly against the input array.

If the default value is passed, then *keepdims* will not be passed through to the *std* method of sub-classes of *ndarray*, however any non-default value will be. If the sub-class' method does not implement *keepdims* any exceptions will be raised.

where

[array_like of bool, optional] Elements to include in the standard deviation. See [reduce](#) for details.

New in version 1.20.0.

mean

[array_like, optional] Provide the mean to prevent its recalculation. The mean should have a shape as if it was calculated with *keepdims*=True. The axis for the calculation of the mean should be the same as used in the call to this std function.

New in version 2.0.0.

correction

[[int, float], optional] Array API compatible name for the *ddof* parameter. Only one of them can be provided at the same time.

New in version 2.0.0.

Returns

standard_deviation

[ndarray, see dtype parameter above.] If *out* is None, return a new array containing the standard deviation, otherwise return a reference to the output array.

See also:

[*var*](#), [*mean*](#), [*nanmean*](#), [*nanstd*](#), [*nanvar*](#)
ufuncs-output-type

Notes

There are several common variants of the array standard deviation calculation. Assuming the input *a* is a one-dimensional NumPy array and *mean* is either provided as an argument or computed as `a.mean()`, NumPy computes the standard deviation of an array as:

```
N = len(a)
d2 = abs(a - mean)**2 # abs is for complex `a`
var = d2.sum() / (N - ddof) # note use of `ddof`
std = var**0.5
```

Different values of the argument *ddof* are useful in different contexts. NumPy's default `ddof=0` corresponds with the expression:

$$\sqrt{\frac{\sum_i |a_i - \bar{a}|^2}{N}}$$

which is sometimes called the “population standard deviation” in the field of statistics because it applies the definition of standard deviation to *a* as if *a* were a complete population of possible observations.

Many other libraries define the standard deviation of an array differently, e.g.:

$$\sqrt{\frac{\sum_i |a_i - \bar{a}|^2}{N - 1}}$$

In statistics, the resulting quantity is sometimes called the “sample standard deviation” because if *a* is a random sample from a larger population, this calculation provides the square root of an unbiased estimate of the variance of the population. The use of $N - 1$ in the denominator is often called “Bessel’s correction” because it corrects for bias (toward lower values) in the variance estimate introduced when the sample mean of *a* is used in place of the true mean of the population. The resulting estimate of the standard deviation is still biased, but less than it would have been without the correction. For this quantity, use `ddof=1`.

Note that, for complex numbers, *std* takes the absolute value before squaring, so that the result is always real and nonnegative.

For floating-point input, the standard deviation is computed using the same precision the input has. Depending on the input data, this can cause the results to be inaccurate, especially for float32 (see example below). Specifying a higher-accuracy accumulator using the *dtype* keyword can alleviate this issue.

Examples

```
>>> import numpy as np
>>> a = np.array([[1, 2], [3, 4]])
>>> np.std(a)
1.1180339887498949 # may vary
>>> np.std(a, axis=0)
array([1., 1.])
>>> np.std(a, axis=1)
array([0.5, 0.5])
```

In single precision, `std()` can be inaccurate:

```
>>> a = np.zeros((2, 512*512), dtype=np.float32)
>>> a[0, :] = 1.0
>>> a[1, :] = 0.1
>>> np.std(a)
np.float32(0.45000005)
```

Computing the standard deviation in float64 is more accurate:

```
>>> np.std(a, dtype=np.float64)
0.44999999925494177 # may vary
```

Specifying a `where` argument:

```
>>> a = np.array([[14, 8, 11, 10], [7, 9, 10, 11], [10, 15, 5, 10]])
>>> np.std(a)
2.614064523559687 # may vary
>>> np.std(a, where=[[True], [True], [False]])
2.0
```

Using the `mean` keyword to save computation time:

```
>>> import numpy as np
>>> from timeit import timeit
>>> a = np.array([[14, 8, 11, 10], [7, 9, 10, 11], [10, 15, 5, 10]])
>>> mean = np.mean(a, axis=1, keepdims=True)
>>>
>>> g = globals()
>>> n = 10000
>>> t1 = timeit("std = np.std(a, axis=1, mean=mean)", globals=g, number=n)
>>> t2 = timeit("std = np.std(a, axis=1)", globals=g, number=n)
>>> print(f'Percentage execution time saved {100*(t2-t1)/t2:.0f}%')

Percentage execution time saved 30%
```

`numpy.var` (*a*, *axis=None*, *dtype=None*, *out=None*, *ddof=0*, *keepdims=<no value>*, *, *where=<no value>*, *mean=<no value>*, *correction=<no value>*)

Compute the variance along the specified axis.

Returns the variance of the array elements, a measure of the spread of a distribution. The variance is computed for the flattened array by default, otherwise over the specified axis.

Parameters

a

[array_like] Array containing numbers whose variance is desired. If *a* is not an array, a conversion is attempted.

axis

[None or int or tuple of ints, optional] Axis or axes along which the variance is computed. The default is to compute the variance of the flattened array. If this is a tuple of ints, a variance is performed over multiple axes, instead of a single axis or all the axes as before.

dtype

[data-type, optional] Type to use in computing the variance. For arrays of integer type the default is `float64`; for arrays of float types it is the same as the array type.

out

[ndarray, optional] Alternate output array in which to place the result. It must have the same shape as the expected output, but the type is cast if necessary.

ddof

[{int, float}, optional] “Delta Degrees of Freedom”: the divisor used in the calculation is $N - \text{ddof}$, where N represents the number of elements. By default `ddof` is zero. See notes for details about use of `ddof`.

keepdims

[bool, optional] If this is set to True, the axes which are reduced are left in the result as dimensions with size one. With this option, the result will broadcast correctly against the input array.

If the default value is passed, then `keepdims` will not be passed through to the `var` method of sub-classes of `ndarray`, however any non-default value will be. If the sub-class’ method does not implement `keepdims` any exceptions will be raised.

where

[array_like of bool, optional] Elements to include in the variance. See `reduce` for details.

New in version 1.20.0.

mean

[array like, optional] Provide the mean to prevent its recalculation. The mean should have a shape as if it was calculated with `keepdims=True`. The axis for the calculation of the mean should be the same as used in the call to this var function.

New in version 2.0.0.

correction

[{int, float}, optional] Array API compatible name for the `ddof` parameter. Only one of them can be provided at the same time.

New in version 2.0.0.

Returns**variance**

[ndarray, see dtype parameter above] If `out=None`, returns a new array containing the variance; otherwise, a reference to the output array is returned.

See also:

`std`, `mean`, `nanmean`, `nanstd`, `nanvar`
ufuncs-output-type

Notes

There are several common variants of the array variance calculation. Assuming the input a is a one-dimensional NumPy array and `mean` is either provided as an argument or computed as `a.mean()`, NumPy computes the variance of an array as:

```
N = len(a)
d2 = abs(a - mean)**2 # abs is for complex `a`
var = d2.sum() / (N - ddof) # note use of `ddof`
```

Different values of the argument `ddof` are useful in different contexts. NumPy’s default `ddof=0` corresponds with the expression:

$$\frac{\sum_i |a_i - \bar{a}|^2}{N}$$

which is sometimes called the “population variance” in the field of statistics because it applies the definition of variance to a as if a were a complete population of possible observations.

Many other libraries define the variance of an array differently, e.g.:

$$\frac{\sum_i |a_i - \bar{a}|^2}{N - 1}$$

In statistics, the resulting quantity is sometimes called the “sample variance” because if a is a random sample from a larger population, this calculation provides an unbiased estimate of the variance of the population. The use of $N - 1$ in the denominator is often called “Bessel’s correction” because it corrects for bias (toward lower values) in the variance estimate introduced when the sample mean of a is used in place of the true mean of the population. For this quantity, use `ddof=1`.

Note that for complex numbers, the absolute value is taken before squaring, so that the result is always real and nonnegative.

For floating-point input, the variance is computed using the same precision the input has. Depending on the input data, this can cause the results to be inaccurate, especially for `float32` (see example below). Specifying a higher-accuracy accumulator using the `dtype` keyword can alleviate this issue.

Examples

```
>>> import numpy as np
>>> a = np.array([[1, 2], [3, 4]])
>>> np.var(a)
1.25
>>> np.var(a, axis=0)
array([1., 1.])
>>> np.var(a, axis=1)
array([0.25, 0.25])
```

In single precision, `var()` can be inaccurate:

```
>>> a = np.zeros((2, 512*512), dtype=np.float32)
>>> a[0, :] = 1.0
>>> a[1, :] = 0.1
>>> np.var(a)
np.float32(0.20250003)
```

Computing the variance in `float64` is more accurate:

```
>>> np.var(a, dtype=np.float64)
0.20249999932944759 # may vary
>>> ((1-0.55)**2 + (0.1-0.55)**2)/2
0.2025
```

Specifying a where argument:

```
>>> a = np.array([[14, 8, 11, 10], [7, 9, 10, 11], [10, 15, 5, 10]])
>>> np.var(a)
6.833333333333333 # may vary
>>> np.var(a, where=[[True], [True], [False]])
4.0
```

Using the mean keyword to save computation time:

```
>>> import numpy as np
>>> from timeit import timeit
>>>
>>> a = np.array([[14, 8, 11, 10], [7, 9, 10, 11], [10, 15, 5, 10]])
>>> mean = np.mean(a, axis=1, keepdims=True)
>>>
>>> g = globals()
>>> n = 10000
>>> t1 = timeit("var = np.var(a, axis=1, mean=mean)", globals=g, number=n)
>>> t2 = timeit("var = np.var(a, axis=1)", globals=g, number=n)
>>> print(f'Percentage execution time saved {100*(t2-t1)/t2:.0f}%')

Percentage execution time saved 32%
```

`numpy.nanmedian(a, axis=None, out=None, overwrite_input=False, keepdims=<no value>)`

Compute the median along the specified axis, while ignoring NaNs.

Returns the median of the array elements.

Parameters

a

[array_like] Input array or object that can be converted to an array.

axis

[{int, sequence of int, None}, optional] Axis or axes along which the medians are computed. The default is to compute the median along a flattened version of the array. A sequence of axes is supported since version 1.9.0.

out

[ndarray, optional] Alternative output array in which to place the result. It must have the same shape and buffer length as the expected output, but the type (of the output) will be cast if necessary.

overwrite_input

[bool, optional] If True, then allow use of memory of input array *a* for calculations. The input array will be modified by the call to *median*. This will save memory when you do not need to preserve the contents of the input array. Treat the input as undefined, but it will probably be fully or partially sorted. Default is False. If *overwrite_input* is True and *a* is not already an *ndarray*, an error will be raised.

keepdims

[bool, optional] If this is set to True, the axes which are reduced are left in the result as dimen-

sions with size one. With this option, the result will broadcast correctly against the original *a*.

If this is anything but the default value it will be passed through (in the special case of an empty array) to the `mean` function of the underlying array. If the array is a sub-class and `mean` does not have the kwarg `keepdims` this will raise a `RuntimeError`.

Returns

median

[ndarray] A new array holding the result. If the input contains integers or floats smaller than `float64`, then the output data-type is `np.float64`. Otherwise, the data-type of the output is the same as that of the input. If *out* is specified, that array is returned instead.

See also:

mean, median, percentile

Notes

Given a vector *V* of length *N*, the median of *V* is the middle value of a sorted copy of *V*, *V_sorted* - i.e., *V_sorted*[(*N*-1)/2], when *N* is odd and the average of the two middle values of *V_sorted* when *N* is even.

Examples

```
>>> import numpy as np
>>> a = np.array([[10.0, 7, 4], [3, 2, 1]])
>>> a[0, 1] = np.nan
>>> a
array([[10., nan, 4.],
       [ 3.,  2.,  1.]])
>>> np.median(a)
np.float64(nan)
>>> np.nanmedian(a)
3.0
>>> np.nanmedian(a, axis=0)
array([6.5, 2. , 2.5])
>>> np.median(a, axis=1)
array([nan,  2.])
>>> b = a.copy()
>>> np.nanmedian(b, axis=1, overwrite_input=True)
array([7.,  2.])
>>> assert not np.all(a==b)
>>> b = a.copy()
>>> np.nanmedian(b, axis=None, overwrite_input=True)
3.0
>>> assert not np.all(a==b)
```

`numpy.nanmean(a, axis=None, dtype=None, out=None, keepdims=<no value>, *, where=<no value>)`

Compute the arithmetic mean along the specified axis, ignoring NaNs.

Returns the average of the array elements. The average is taken over the flattened array by default, otherwise over the specified axis. `float64` intermediate and return values are used for integer inputs.

For all-NaN slices, NaN is returned and a *RuntimeWarning* is raised.

Parameters

a
[array_like] Array containing numbers whose mean is desired. If *a* is not an array, a conversion is attempted.

axis
[{int, tuple of int, None}, optional] Axis or axes along which the means are computed. The default is to compute the mean of the flattened array.

dtype
[data-type, optional] Type to use in computing the mean. For integer inputs, the default is `float64`; for inexact inputs, it is the same as the input dtype.

out
[ndarray, optional] Alternate output array in which to place the result. The default is `None`; if provided, it must have the same shape as the expected output, but the type will be cast if necessary. See `ufuncs-output-type` for more details.

keepdims
[bool, optional] If this is set to `True`, the axes which are reduced are left in the result as dimensions with size one. With this option, the result will broadcast correctly against the original *a*.

If the value is anything but the default, then *keepdims* will be passed through to the `mean` or `sum` methods of sub-classes of `ndarray`. If the sub-classes methods does not implement *keepdims* any exceptions will be raised.

where
[array_like of bool, optional] Elements to include in the mean. See `reduce` for details.

New in version 1.22.0.

Returns

m
[ndarray, see dtype parameter above] If *out=None*, returns a new array containing the mean values, otherwise a reference to the output array is returned. `NaN` is returned for slices that contain only `NaN`s.

See also:

`average`
Weighted average

`mean`
Arithmetic mean taken while not ignoring `NaN`s

`var`, `nanvar`

Notes

The arithmetic mean is the sum of the non-`NaN` elements along the axis divided by the number of non-`NaN` elements.

Note that for floating-point input, the mean is computed using the same precision the input has. Depending on the input data, this can cause the results to be inaccurate, especially for `float32`. Specifying a higher-precision accumulator using the *dtype* keyword can alleviate this issue.

Examples

```
>>> import numpy as np
>>> a = np.array([[1, np.nan], [3, 4]])
>>> np.nanmean(a)
2.6666666666666665
>>> np.nanmean(a, axis=0)
array([2., 4.])
>>> np.nanmean(a, axis=1)
array([1., 3.5]) # may vary
```

`numpy.nanstd` (*a*, *axis=None*, *dtype=None*, *out=None*, *ddof=0*, *keepdims=<no value>*, ***, *where=<no value>*, *mean=<no value>*, *correction=<no value>*)

Compute the standard deviation along the specified axis, while ignoring NaNs.

Returns the standard deviation, a measure of the spread of a distribution, of the non-NaN array elements. The standard deviation is computed for the flattened array by default, otherwise over the specified axis.

For all-NaN slices or slices with zero degrees of freedom, NaN is returned and a *RuntimeWarning* is raised.

Parameters

a

[array_like] Calculate the standard deviation of the non-NaN values.

axis

[{int, tuple of int, None}, optional] Axis or axes along which the standard deviation is computed. The default is to compute the standard deviation of the flattened array.

dtype

[dtype, optional] Type to use in computing the standard deviation. For arrays of integer type the default is float64, for arrays of float types it is the same as the array type.

out

[ndarray, optional] Alternative output array in which to place the result. It must have the same shape as the expected output but the type (of the calculated values) will be cast if necessary.

ddof

[{int, float}, optional] Means Delta Degrees of Freedom. The divisor used in calculations is $N - \text{ddof}$, where N represents the number of non-NaN elements. By default *ddof* is zero.

keepdims

[bool, optional] If this is set to True, the axes which are reduced are left in the result as dimensions with size one. With this option, the result will broadcast correctly against the original *a*.

If this value is anything but the default it is passed through as-is to the relevant functions of the sub-classes. If these functions do not have a *keepdims* kwarg, a *RuntimeError* will be raised.

where

[array_like of bool, optional] Elements to include in the standard deviation. See [reduce](#) for details.

New in version 1.22.0.

mean

[array_like, optional] Provide the mean to prevent its recalculation. The mean should have a shape as if it was calculated with *keepdims=True*. The axis for the calculation of the mean should be the same as used in the call to this std function.

New in version 2.0.0.

correction

[[int, float], optional] Array API compatible name for the `ddof` parameter. Only one of them can be provided at the same time.

New in version 2.0.0.

Returns**standard_deviation**

[ndarray, see dtype parameter above.] If `out` is None, return a new array containing the standard deviation, otherwise return a reference to the output array. If `ddof` is $\geq$ the number of non-NaN elements in a slice or the slice contains only NaNs, then the result for that slice is NaN.

See also:

[`var`](#), [`mean`](#), [`std`](#)
[`nanvar`](#), [`nanmean`](#)
[`ufuncs-output-type`](#)

Notes

The standard deviation is the square root of the average of the squared deviations from the mean: `std = sqrt(mean(abs(x - x.mean())**2))`.

The average squared deviation is normally calculated as `x.sum() / N`, where `N = len(x)`. If, however, `ddof` is specified, the divisor `N - ddof` is used instead. In standard statistical practice, `ddof=1` provides an unbiased estimator of the variance of the infinite population. `ddof=0` provides a maximum likelihood estimate of the variance for normally distributed variables. The standard deviation computed in this function is the square root of the estimated variance, so even with `ddof=1`, it will not be an unbiased estimate of the standard deviation per se.

Note that, for complex numbers, `std` takes the absolute value before squaring, so that the result is always real and nonnegative.

For floating-point input, the `std` is computed using the same precision the input has. Depending on the input data, this can cause the results to be inaccurate, especially for float32 (see example below). Specifying a higher-accuracy accumulator using the `dtype` keyword can alleviate this issue.

Examples

```
>>> import numpy as np
>>> a = np.array([[1, np.nan], [3, 4]])
>>> np.nanstd(a)
1.247219128924647
>>> np.nanstd(a, axis=0)
array([1., 0.])
>>> np.nanstd(a, axis=1)
array([0., 0.5]) # may vary
```

`numpy.nanvar` (`a`, `axis=None`, `dtype=None`, `out=None`, `ddof=0`, `keepdims=<no value>`, `*`, `where=<no value>`, `mean=<no value>`, `correction=<no value>`)

Compute the variance along the specified axis, while ignoring NaNs.

Returns the variance of the array elements, a measure of the spread of a distribution. The variance is computed for the flattened array by default, otherwise over the specified axis.

For all-NaN slices or slices with zero degrees of freedom, NaN is returned and a *RuntimeWarning* is raised.

Parameters**a**

[array_like] Array containing numbers whose variance is desired. If *a* is not an array, a conversion is attempted.

axis

[{int, tuple of int, None}, optional] Axis or axes along which the variance is computed. The default is to compute the variance of the flattened array.

dtype

[data-type, optional] Type to use in computing the variance. For arrays of integer type the default is `float64`; for arrays of float types it is the same as the array type.

out

[ndarray, optional] Alternate output array in which to place the result. It must have the same shape as the expected output, but the type is cast if necessary.

ddof

[{int, float}, optional] “Delta Degrees of Freedom”: the divisor used in the calculation is $N - \text{ddof}$, where *N* represents the number of non-NaN elements. By default *ddof* is zero.

keepdims

[bool, optional] If this is set to True, the axes which are reduced are left in the result as dimensions with size one. With this option, the result will broadcast correctly against the original *a*.

where

[array_like of bool, optional] Elements to include in the variance. See [reduce](#) for details.

New in version 1.22.0.

mean

[array_like, optional] Provide the mean to prevent its recalculation. The mean should have a shape as if it was calculated with `keepdims=True`. The axis for the calculation of the mean should be the same as used in the call to this var function.

New in version 2.0.0.

correction

[{int, float}, optional] Array API compatible name for the *ddof* parameter. Only one of them can be provided at the same time.

New in version 2.0.0.

Returns**variance**

[ndarray, see dtype parameter above] If *out* is None, return a new array containing the variance, otherwise return a reference to the output array. If *ddof* is $\geq$ the number of non-NaN elements in a slice or the slice contains only NaNs, then the result for that slice is NaN.

See also:[*std*](#)

Standard deviation

[*mean*](#)

Average

[*var*](#)

Variance while not ignoring NaNs

`nanstd`, `nanmean`
ufuncs-output-type

Notes

The variance is the average of the squared deviations from the mean, i.e., `var = mean(abs(x - x.mean())**2)`.

The mean is normally calculated as `x.sum() / N`, where `N = len(x)`. If, however, `ddof` is specified, the divisor `N - ddof` is used instead. In standard statistical practice, `ddof=1` provides an unbiased estimator of the variance of a hypothetical infinite population. `ddof=0` provides a maximum likelihood estimate of the variance for normally distributed variables.

Note that for complex numbers, the absolute value is taken before squaring, so that the result is always real and nonnegative.

For floating-point input, the variance is computed using the same precision the input has. Depending on the input data, this can cause the results to be inaccurate, especially for `float32` (see example below). Specifying a higher-accuracy accumulator using the `dtype` keyword can alleviate this issue.

For this function to work on sub-classes of `ndarray`, they must define `sum` with the kwarg `keepdims`

Examples

```
>>> import numpy as np
>>> a = np.array([[1, np.nan], [3, 4]])
>>> np.nanvar(a)
1.5555555555555554
>>> np.nanvar(a, axis=0)
array([1.,  0.])
>>> np.nanvar(a, axis=1)
array([0.,  0.25]) # may vary
```

Correlating

<code>corrcoef(x[, y, rowvar, dtype])</code>	Return Pearson product-moment correlation coefficients.
<code>correlate(a, v[, mode])</code>	Cross-correlation of two 1-dimensional sequences.
<code>cov(m[, y, rowvar, bias, ddof, fweights, ...])</code>	Estimate a covariance matrix, given data and weights.

`numpy.corrcoef(x, y=None, rowvar=True, *, dtype=None)`

Return Pearson product-moment correlation coefficients.

Please refer to the documentation for `cov` for more detail. The relationship between the correlation coefficient matrix, R , and the covariance matrix, C , is

$$R_{ij} = \frac{C_{ij}}{\sqrt{C_{ii}C_{jj}}}$$

The values of R are between -1 and 1, inclusive.

Parameters

x

[array_like] A 1-D or 2-D array containing multiple variables and observations. Each row of *x* represents a variable, and each column a single observation of all those variables. Also see *rowvar* below.

y

[array_like, optional] An additional set of variables and observations. *y* has the same shape as *x*.

rowvar

[bool, optional] If *rowvar* is True (default), then each row represents a variable, with observations in the columns. Otherwise, the relationship is transposed: each column represents a variable, while the rows contain observations.

dtype

[data-type, optional] Data-type of the result. By default, the return data-type will have at least *numpy.float64* precision.

New in version 1.20.

Returns

R

[ndarray] The correlation coefficient matrix of the variables.

See also:

cov

Covariance matrix

Notes

Due to floating point rounding the resulting array may not be Hermitian, the diagonal elements may not be 1, and the elements may not satisfy the inequality $\text{abs}(a) \leq 1$. The real and imaginary parts are clipped to the interval $[-1, 1]$ in an attempt to improve on that situation but is not much help in the complex case.

Examples

```
>>> import numpy as np
```

In this example we generate two random arrays, *xarr* and *yarr*, and compute the row-wise and column-wise Pearson correlation coefficients, *R*. Since *rowvar* is true by default, we first find the row-wise Pearson correlation coefficients between the variables of *xarr*.

```
>>> import numpy as np
>>> rng = np.random.default_rng(seed=42)
>>> xarr = rng.random((3, 3))
>>> xarr
array([[0.77395605, 0.43887844, 0.85859792],
       [0.69736803, 0.09417735, 0.97562235],
       [0.7611397 , 0.78606431, 0.12811363]])
>>> R1 = np.corrcoef(xarr)
>>> R1
array([[ 1.          ,  0.99256089, -0.68080986],
       [ 0.99256089,  1.          , -0.76492172],
       [-0.68080986, -0.76492172,  1.          ]])
```

If we add another set of variables and observations `yarr`, we can compute the row-wise Pearson correlation coefficients between the variables in `xarr` and `yarr`.

```
>>> yarr = rng.random((3, 3))
>>> yarr
array([[0.45038594, 0.37079802, 0.92676499],
       [0.64386512, 0.82276161, 0.4434142 ],
       [0.22723872, 0.55458479, 0.06381726]])
>>> R2 = np.corrcoef(xarr, yarr)
>>> R2
array([[ 1.          ,  0.99256089, -0.68080986,  0.75008178, -0.934284  ,
        -0.99004057],
       [ 0.99256089,  1.          , -0.76492172,  0.82502011, -0.97074098,
        -0.99981569],
       [-0.68080986, -0.76492172,  1.          , -0.99507202,  0.89721355,
         0.77714685],
       [ 0.75008178,  0.82502011, -0.99507202,  1.          , -0.93657855,
        -0.83571711],
       [-0.934284  , -0.97074098,  0.89721355, -0.93657855,  1.          ,
         0.97517215],
       [-0.99004057, -0.99981569,  0.77714685, -0.83571711,  0.97517215,
         1.          ]])
```

Finally if we use the option `rowvar=False`, the columns are now being treated as the variables and we will find the column-wise Pearson correlation coefficients between variables in `xarr` and `yarr`.

```
>>> R3 = np.corrcoef(xarr, yarr, rowvar=False)
>>> R3
array([[ 1.          ,  0.77598074, -0.47458546, -0.75078643, -0.9665554 ,
         0.22423734],
       [ 0.77598074,  1.          , -0.92346708, -0.99923895, -0.58826587,
        -0.44069024],
       [-0.47458546, -0.92346708,  1.          ,  0.93773029,  0.23297648,
         0.75137473],
       [-0.75078643, -0.99923895,  0.93773029,  1.          ,  0.55627469,
         0.47536961],
       [-0.9665554 , -0.58826587,  0.23297648,  0.55627469,  1.          ,
        -0.46666491],
       [ 0.22423734, -0.44069024,  0.75137473,  0.47536961, -0.46666491,
         1.          ]])
```

`numpy.correlate(a, v, mode='valid')`

Cross-correlation of two 1-dimensional sequences.

This function computes the correlation as generally defined in signal processing texts [1]:

$$c_k = \sum_n a_{n+k} \cdot \bar{v}_n$$

with `a` and `v` sequences being zero-padded where necessary and $\bar{v}$ denoting complex conjugation.

Parameters

a, v

[array_like] Input sequences.

mode

[{'valid', 'same', 'full'}, optional] Refer to the [convolve](#) docstring. Note that the default is 'valid', unlike [convolve](#), which uses 'full'.

Returns**out**[ndarray] Discrete cross-correlation of a and v .**See also:****`convolve`**

Discrete, linear convolution of two one-dimensional sequences.

`scipy.signal.correlate`

uses FFT which has superior performance on large arrays.

Notes

The definition of correlation above is not unique and sometimes correlation may be defined differently. Another common definition is [1]:

$$c'_k = \sum_n a_n \cdot \overline{v_{n+k}}$$

which is related to c_k by $c'_k = c_{-k}$.

`numpy.correlate` may perform slowly in large arrays (i.e. $n = 1e5$) because it does not use the FFT to compute the convolution; in that case, `scipy.signal.correlate` might be preferable.

References

[1]

Examples

```
>>> import numpy as np
>>> np.correlate([1, 2, 3], [0, 1, 0.5])
array([3.5])
>>> np.correlate([1, 2, 3], [0, 1, 0.5], "same")
array([2. , 3.5, 3. ])
>>> np.correlate([1, 2, 3], [0, 1, 0.5], "full")
array([0.5, 2. , 3.5, 3. , 0. ])
```

Using complex sequences:

```
>>> np.correlate([1+1j, 2, 3-1j], [0, 1, 0.5j], 'full')
array([ 0.5-0.5j,  1.0+0.j ,  1.5-1.5j,  3.0-1.j ,  0.0+0.j ])
```

Note that you get the time reversed, complex conjugated result ($\overline{c_{-k}}$) when the two input sequences a and v change places:

```
>>> np.correlate([0, 1, 0.5j], [1+1j, 2, 3-1j], 'full')
array([ 0.0+0.j ,  3.0+1.j ,  1.5+1.5j,  1.0+0.j ,  0.5+0.5j])
```

`numpy.cov(m, y=None, rowvar=True, bias=False, ddof=None, fweights=None, aweights=None, *, dtype=None)`

Estimate a covariance matrix, given data and weights.

Covariance indicates the level to which two variables vary together. If we examine N-dimensional samples, $X = [x_1, x_2, \dots, x_N]^T$, then the covariance matrix element C_{ij} is the covariance of x_i and x_j . The element C_{ii} is the variance of x_i .

See the notes for an outline of the algorithm.

Parameters

m

[array_like] A 1-D or 2-D array containing multiple variables and observations. Each row of *m* represents a variable, and each column a single observation of all those variables. Also see *rowvar* below.

y

[array_like, optional] An additional set of variables and observations. *y* has the same form as that of *m*.

rowvar

[bool, optional] If *rowvar* is True (default), then each row represents a variable, with observations in the columns. Otherwise, the relationship is transposed: each column represents a variable, while the rows contain observations.

bias

[bool, optional] Default normalization (False) is by $(N - 1)$, where *N* is the number of observations given (unbiased estimate). If *bias* is True, then normalization is by *N*. These values can be overridden by using the keyword *ddof* in numpy versions ≥ 1.5 .

ddof

[int, optional] If not None the default value implied by *bias* is overridden. Note that *ddof*=1 will return the unbiased estimate, even if both *fweights* and *aweights* are specified, and *ddof*=0 will return the simple average. See the notes for the details. The default value is None.

fweights

[array_like, int, optional] 1-D array of integer frequency weights; the number of times each observation vector should be repeated.

aweights

[array_like, optional] 1-D array of observation vector weights. These relative weights are typically large for observations considered “important” and smaller for observations considered less “important”. If *ddof*=0 the array of weights can be used to assign probabilities to observation vectors.

dtype

[data-type, optional] Data-type of the result. By default, the return data-type will have at least *numpy.float64* precision.

New in version 1.20.

Returns

out

[ndarray] The covariance matrix of the variables.

See also:

corrcoef

Normalized covariance matrix

Notes

Assume that the observations are in the columns of the observation array m and let $f = fweights$ and $a = aweights$ for brevity. The steps to compute the weighted covariance are as follows:

```
>>> m = np.arange(10, dtype=np.float64)
>>> f = np.arange(10) * 2
>>> a = np.arange(10) ** 2.
>>> ddof = 1
>>> w = f * a
>>> v1 = np.sum(w)
>>> v2 = np.sum(w * a)
>>> m -= np.sum(m * w, axis=None, keepdims=True) / v1
>>> cov = np.dot(m * w, m.T) * v1 / (v1**2 - ddof * v2)
```

Note that when $a == 1$, the normalization factor $v1 / (v1**2 - ddof * v2)$ goes over to $1 / (np.sum(f) - ddof)$ as it should.

Examples

```
>>> import numpy as np
```

Consider two variables, x_0 and x_1 , which correlate perfectly, but in opposite directions:

```
>>> x = np.array([[0, 2], [1, 1], [2, 0]]).T
>>> x
array([[0, 1, 2],
       [2, 1, 0]])
```

Note how x_0 increases while x_1 decreases. The covariance matrix shows this clearly:

```
>>> np.cov(x)
array([[ 1., -1.],
       [-1.,  1.]])
```

Note that element $C_{0,1}$, which shows the correlation between x_0 and x_1 , is negative.

Further, note how x and y are combined:

```
>>> x = [-2.1, -1, 4.3]
>>> y = [3, 1.1, 0.12]
>>> X = np.stack((x, y), axis=0)
>>> np.cov(X)
array([[11.71      , -4.286      ], # may vary
       [-4.286      ,  2.144133]])
>>> np.cov(x, y)
array([[11.71      , -4.286      ], # may vary
       [-4.286      ,  2.144133]])
>>> np.cov(x)
array(11.71)
```

Histograms

<code>histogram(a[, bins, range, density, weights])</code>	Compute the histogram of a dataset.
<code>histogram2d(x, y[, bins, range, density, ...])</code>	Compute the bi-dimensional histogram of two data samples.
<code>histogramdd(sample[, bins, range, density, ...])</code>	Compute the multidimensional histogram of some data.
<code>bincount(x, /[, weights, minlength])</code>	Count number of occurrences of each value in array of non-negative ints.
<code>histogram_bin_edges(a[, bins, range, weights])</code>	Function to calculate only the edges of the bins used by the <code>histogram</code> function.
<code>digitize(x, bins[, right])</code>	Return the indices of the bins to which each value in input array belongs.

`numpy.histogram(a, bins=10, range=None, density=None, weights=None)`

Compute the histogram of a dataset.

Parameters

a

[array_like] Input data. The histogram is computed over the flattened array.

bins

[int or sequence of scalars or str, optional] If *bins* is an int, it defines the number of equal-width bins in the given range (10, by default). If *bins* is a sequence, it defines a monotonically increasing array of bin edges, including the rightmost edge, allowing for non-uniform bin widths.

If *bins* is a string, it defines the method used to calculate the optimal bin width, as defined by `histogram_bin_edges`.

range

[(float, float), optional] The lower and upper range of the bins. If not provided, range is simply `(a.min(), a.max())`. Values outside the range are ignored. The first element of the range must be less than or equal to the second. *range* affects the automatic bin computation as well. While bin width is computed to be optimal based on the actual data within *range*, the bin count will fill the entire range including portions containing no data.

weights

[array_like, optional] An array of weights, of the same shape as *a*. Each value in *a* only contributes its associated weight towards the bin count (instead of 1). If *density* is True, the weights are normalized, so that the integral of the density over the range remains 1. Please note that the `dtype` of *weights* will also become the `dtype` of the returned accumulator (*hist*), so it must be large enough to hold accumulated values as well.

density

[bool, optional] If False, the result will contain the number of samples in each bin. If True, the result is the value of the probability *density* function at the bin, normalized such that the *integral* over the range is 1. Note that the sum of the histogram values will not be equal to 1 unless bins of unity width are chosen; it is not a probability *mass* function.

Returns

hist

[array] The values of the histogram. See *density* and *weights* for a description of the possible semantics. If *weights* are given, `hist.dtype` will be taken from *weights*.

bin_edges

[array of dtype float] Return the bin edges `(length(hist)+1)`.

See also:

[*histogramdd*](#), [*bincount*](#), [*searchsorted*](#), [*digitize*](#), [*histogram_bin_edges*](#)

Notes

All but the last (righthand-most) bin is half-open. In other words, if *bins* is:

```
[1, 2, 3, 4]
```

then the first bin is `[1, 2)` (including 1, but excluding 2) and the second `[2, 3)`. The last bin, however, is `[3, 4]`, which *includes* 4.

Examples

```
>>> import numpy as np
>>> np.histogram([1, 2, 1], bins=[0, 1, 2, 3])
(array([0, 2, 1]), array([0, 1, 2, 3]))
>>> np.histogram(np.arange(4), bins=np.arange(5), density=True)
(array([0.25, 0.25, 0.25, 0.25]), array([0, 1, 2, 3, 4]))
>>> np.histogram([1, 2, 1], [1, 0, 1], bins=[0,1,2,3])
(array([1, 4, 1]), array([0, 1, 2, 3]))
```

```
>>> a = np.arange(5)
>>> hist, bin_edges = np.histogram(a, density=True)
>>> hist
array([0.5, 0. , 0.5, 0. , 0. , 0.5, 0. , 0.5, 0. , 0.5])
>>> hist.sum()
2.4999999999999996
>>> np.sum(hist * np.diff(bin_edges))
1.0
```

Automated Bin Selection Methods example, using 2 peak random data with 2000 points.

```
import matplotlib.pyplot as plt
import numpy as np

rng = np.random.RandomState(10) # deterministic random data
a = np.hstack((rng.normal(size=1000),
               rng.normal(loc=5, scale=2, size=1000)))
plt.hist(a, bins='auto') # arguments are passed to np.histogram
plt.title("Histogram with 'auto' bins")
plt.show()
```

`numpy.histogram2d(x, y, bins=10, range=None, density=None, weights=None)`

Compute the bi-dimensional histogram of two data samples.

Parameters

x

[array_like, shape (N,)] An array containing the x coordinates of the points to be histogrammed.

y

[array_like, shape (N,)] An array containing the y coordinates of the points to be histogrammed.

**bins**

[int or array_like or [int, int] or [array, array], optional] The bin specification:

- If int, the number of bins for the two dimensions (nx=ny=bins).
- If array_like, the bin edges for the two dimensions (x_edges=y_edges=bins).
- If [int, int], the number of bins in each dimension (nx, ny = bins).
- If [array, array], the bin edges in each dimension (x_edges, y_edges = bins).
- A combination [int, array] or [array, int], where int is the number of bins and array is the bin edges.

range

[array_like, shape(2,2), optional] The leftmost and rightmost edges of the bins along each dimension (if not specified explicitly in the *bins* parameters): `[[xmin, xmax], [ymin, ymax]]`. All values outside of this range will be considered outliers and not tallied in the histogram.

density

[bool, optional] If False, the default, returns the number of samples in each bin. If True, returns the probability *density* function at the bin, `bin_count / sample_count / bin_area`.

weights

[array_like, shape(N,), optional] An array of values `w_i` weighing each sample `(x_i, y_i)`. Weights are normalized to 1 if *density* is True. If *density* is False, the values of the returned histogram are equal to the sum of the weights belonging to the samples falling into each bin.

Returns**H**

[ndarray, shape(nx, ny)] The bi-dimensional histogram of samples *x* and *y*. Values in *x* are histogrammed along the first dimension and values in *y* are histogrammed along the second dimension.

xedges

[ndarray, shape(nx+1,)] The bin edges along the first dimension.

yedges

[ndarray, shape(ny+1,)] The bin edges along the second dimension.

See also:

histogram

1D histogram

histogramdd

Multidimensional histogram

Notes

When *density* is True, then the returned histogram is the sample density, defined such that the sum over bins of the product `bin_value * bin_area` is 1.

Please note that the histogram does not follow the Cartesian convention where *x* values are on the abscissa and *y* values on the ordinate axis. Rather, *x* is histogrammed along the first dimension of the array (vertical), and *y* along the second dimension of the array (horizontal). This ensures compatibility with *histogramdd*.

Examples

```
>>> import numpy as np
>>> from matplotlib.image import NonUniformImage
>>> import matplotlib.pyplot as plt
```

Construct a 2-D histogram with variable bin width. First define the bin edges:

```
>>> xedges = [0, 1, 3, 5]
>>> yedges = [0, 2, 3, 4, 6]
```

Next we create a histogram *H* with random bin content:

```
>>> x = np.random.normal(2, 1, 100)
>>> y = np.random.normal(1, 1, 100)
>>> H, xedges, yedges = np.histogram2d(x, y, bins=(xedges, yedges))
>>> # Histogram does not follow Cartesian convention (see Notes),
>>> # therefore transpose H for visualization purposes.
>>> H = H.T
```

imshow can only display square bins:

```
>>> fig = plt.figure(figsize=(7, 3))
>>> ax = fig.add_subplot(131, title='imshow: square bins')
>>> plt.imshow(H, interpolation='nearest', origin='lower',
...           extent=[xedges[0], xedges[-1], yedges[0], yedges[-1]])
<matplotlib.image.AxesImage object at 0x...>
```

pcolormesh can display actual edges:

```
>>> ax = fig.add_subplot(132, title='pcolormesh: actual edges',
...                       aspect='equal')
>>> X, Y = np.meshgrid(xedges, yedges)
>>> ax.pcolormesh(X, Y, H)
<matplotlib.collections.QuadMesh object at 0x...>
```

`NonUniformImage` can be used to display actual bin edges with interpolation:

```
>>> ax = fig.add_subplot(133, title='NonUniformImage: interpolated',
...     aspect='equal', xlim=xedges[[0, -1]], ylim=yedges[[0, -1]])
>>> im = NonUniformImage(ax, interpolation='bilinear')
>>> xcenters = (xedges[:-1] + xedges[1:]) / 2
>>> ycenters = (yedges[:-1] + yedges[1:]) / 2
>>> im.set_data(xcenters, ycenters, H)
>>> ax.add_image(im)
>>> plt.show()
```

It is also possible to construct a 2-D histogram without specifying bin edges:

```
>>> # Generate non-symmetric test data
>>> n = 10000
>>> x = np.linspace(1, 100, n)
>>> y = 2*np.log(x) + np.random.rand(n) - 0.5
>>> # Compute 2d histogram. Note the order of x/y and xedges/yedges
>>> H, yedges, xedges = np.histogram2d(y, x, bins=20)
```

Now we can plot the histogram using `pcolormesh`, and a `hexbin` for comparison.

```
>>> # Plot histogram using pcolormesh
>>> fig, (ax1, ax2) = plt.subplots(ncols=2, sharey=True)
>>> ax1.pcolormesh(xedges, yedges, H, cmap='rainbow')
>>> ax1.plot(x, 2*np.log(x), 'k-')
>>> ax1.set_xlim(x.min(), x.max())
>>> ax1.set_ylim(y.min(), y.max())
>>> ax1.set_xlabel('x')
>>> ax1.set_ylabel('y')
>>> ax1.set_title('histogram2d')
>>> ax1.grid()
```

```
>>> # Create hexbin plot for comparison
>>> ax2.hexbin(x, y, gridsize=20, cmap='rainbow')
>>> ax2.plot(x, 2*np.log(x), 'k-')
>>> ax2.set_title('hexbin')
>>> ax2.set_xlim(x.min(), x.max())
```

(continues on next page)

(continued from previous page)

```
>>> ax2.set_xlabel('x')
>>> ax2.grid()
```

```
>>> plt.show()
```

`numpy.histogramdd` (*sample*, *bins*=10, *range*=None, *density*=None, *weights*=None)

Compute the multidimensional histogram of some data.

Parameters

sample

[(N, D) array, or (N, D) array_like] The data to be histogrammed.

Note the unusual interpretation of sample when an array_like:

- When an array, each row is a coordinate in a D-dimensional space - such as `histogramdd(np.array([p1, p2, p3]))`.
- When an array_like, each element is the list of values for single coordinate - such as `histogramdd((X, Y, Z))`.

The first form should be preferred.

bins

[sequence or int, optional] The bin specification:

- A sequence of arrays describing the monotonically increasing bin edges along each dimension.
- The number of bins for each dimension (`nx, ny, ... =bins`)
- The number of bins for all dimensions (`nx=ny=...=bins`).

range

[sequence, optional] A sequence of length D, each an optional (lower, upper) tuple giving the outer bin edges to be used if the edges are not given explicitly in *bins*. An entry of None in the sequence results in the minimum and maximum values being used for the corresponding dimension. The default, None, is equivalent to passing a tuple of D None values.

density

[bool, optional] If False, the default, returns the number of samples in each bin. If True, returns the probability *density* function at the bin, $\text{bin_count} / \text{sample_count} / \text{bin_volume}$.

weights

[(N,) array_like, optional] An array of values w_i weighing each sample $(x_i, y_i, z_i, \dots)$. Weights are normalized to 1 if density is True. If density is False, the values of the returned histogram are equal to the sum of the weights belonging to the samples falling into each bin.

Returns**H**

[ndarray] The multidimensional histogram of sample x . See density and weights for the different possible semantics.

edges

[tuple of ndarrays] A tuple of D arrays describing the bin edges for each dimension.

See also:

histogram

1-D histogram

histogram2d

2-D histogram

Examples

```
>>> import numpy as np
>>> rng = np.random.default_rng()
>>> r = rng.normal(size=(100,3))
>>> H, edges = np.histogramdd(r, bins = (5, 8, 4))
>>> H.shape, edges[0].size, edges[1].size, edges[2].size
((5, 8, 4), 6, 9, 5)
```

`numpy.bincount` (x , /, *weights=None*, *minlength=0*)

Count number of occurrences of each value in array of non-negative ints.

The number of bins (of size 1) is one larger than the largest value in x . If *minlength* is specified, there will be at least this number of bins in the output array (though it will be longer if necessary, depending on the contents of x). Each bin gives the number of occurrences of its index value in x . If *weights* is specified the input array is weighted by it, i.e. if a value n is found at position i , $\text{out}[n] += \text{weight}[i]$ instead of $\text{out}[n] += 1$.

Parameters**x**

[array_like, 1 dimension, nonnegative ints] Input array.

weights

[array_like, optional] Weights, array of the same shape as x .

minlength

[int, optional] A minimum number of bins for the output array.

Returns**out**

[ndarray of ints] The result of binning the input array. The length of *out* is equal to $\text{np.amax}(x) + 1$.

Raises**ValueError**

If the input is not 1-dimensional, or contains elements with negative values, or if *minlength* is negative.

TypeError

If the type of the input is float or complex.

See also:

histogram, *digitize*, *unique*

Examples

```
>>> import numpy as np
>>> np.bincount(np.arange(5))
array([1, 1, 1, 1, 1])
>>> np.bincount(np.array([0, 1, 1, 3, 2, 1, 7]))
array([1, 3, 1, 1, 0, 0, 0, 1])
```

```
>>> x = np.array([0, 1, 1, 3, 2, 1, 7, 23])
>>> np.bincount(x).size == np.amax(x)+1
True
```

The input array needs to be of integer dtype, otherwise a `TypeError` is raised:

```
>>> np.bincount(np.arange(5, dtype=np.float64))
Traceback (most recent call last):
...
TypeError: Cannot cast array data from dtype('float64') to dtype('int64')
according to the rule 'safe'
```

A possible use of `bincount` is to perform sums over variable-size chunks of an array, using the `weights` keyword.

```
>>> w = np.array([0.3, 0.5, 0.2, 0.7, 1., -0.6]) # weights
>>> x = np.array([0, 1, 1, 2, 2, 2])
>>> np.bincount(x, weights=w)
array([ 0.3,  0.7,  1.1])
```

`numpy.histogram_bin_edges` (*a*, *bins*=10, *range*=None, *weights*=None)

Function to calculate only the edges of the bins used by the *histogram* function.

Parameters**a**

[array_like] Input data. The histogram is computed over the flattened array.

bins

[int or sequence of scalars or str, optional] If *bins* is an int, it defines the number of equal-width bins in the given range (10, by default). If *bins* is a sequence, it defines the bin edges, including the rightmost edge, allowing for non-uniform bin widths.

If *bins* is a string from the list below, *histogram_bin_edges* will use the method chosen to calculate the optimal bin width and consequently the number of bins (see the Notes section for more detail on the estimators) from the data that falls within the requested range. While the bin width will be optimal for the actual data in the range, the number of bins will be computed

to fill the entire range, including the empty portions. For visualisation, using the 'auto' option is suggested. Weighted data is not supported for automated bin size selection.

'auto'

Minimum bin width between the 'sturges' and 'fd' estimators. Provides good all-around performance.

'fd' (Freedman Diaconis Estimator)

Robust (resilient to outliers) estimator that takes into account data variability and data size.

'doane'

An improved version of Sturges' estimator that works better with non-normal datasets.

'scott'

Less robust estimator that takes into account data variability and data size.

'stone'

Estimator based on leave-one-out cross-validation estimate of the integrated squared error. Can be regarded as a generalization of Scott's rule.

'rice'

Estimator does not take variability into account, only data size. Commonly overestimates number of bins required.

'sturges'

R's default method, only accounts for data size. Only optimal for gaussian data and underestimates number of bins for large non-gaussian datasets.

'sqrt'

Square root (of data size) estimator, used by Excel and other programs for its speed and simplicity.

range

[(float, float), optional] The lower and upper range of the bins. If not provided, range is simply `(a.min(), a.max())`. Values outside the range are ignored. The first element of the range must be less than or equal to the second. *range* affects the automatic bin computation as well. While bin width is computed to be optimal based on the actual data within *range*, the bin count will fill the entire range including portions containing no data.

weights

[array_like, optional] An array of weights, of the same shape as *a*. Each value in *a* only contributes its associated weight towards the bin count (instead of 1). This is currently not used by any of the bin estimators, but may be in the future.

Returns

bin_edges

[array of dtype float] The edges to pass into *histogram*

See also:

histogram

Notes

The methods to estimate the optimal number of bins are well founded in literature, and are inspired by the choices R provides for histogram visualisation. Note that having the number of bins proportional to $n^{1/3}$ is asymptotically optimal, which is why it appears in most estimators. These are simply plug-in methods that give good starting points for number of bins. In the equations below, h is the binwidth and n_h is the number of bins. All estimators that compute bin counts are recast to bin width using the `ptp` of the data. The final bin count is obtained from `np.round(np.ceil(range / h))`. The final bin width is often less than what is returned by the estimators below.

‘auto’ (minimum bin width of the ‘sturges’ and ‘fd’ estimators)

A compromise to get a good value. For small datasets the Sturges value will usually be chosen, while larger datasets will usually default to FD. Avoids the overly conservative behaviour of FD and Sturges for small and large datasets respectively. Switchover point is usually `a.size` $\approx$ 1000.

‘fd’ (Freedman Diaconis Estimator)

$$h = 2 \frac{IQR}{n^{1/3}}$$

The binwidth is proportional to the interquartile range (IQR) and inversely proportional to cube root of `a.size`. Can be too conservative for small datasets, but is quite good for large datasets. The IQR is very robust to outliers.

‘scott’

$$h = \sigma \sqrt[3]{\frac{24\sqrt{\pi}}{n}}$$

The binwidth is proportional to the standard deviation of the data and inversely proportional to cube root of `x.size`. Can be too conservative for small datasets, but is quite good for large datasets. The standard deviation is not very robust to outliers. Values are very similar to the Freedman-Diaconis estimator in the absence of outliers.

‘rice’

$$n_h = 2n^{1/3}$$

The number of bins is only proportional to cube root of `a.size`. It tends to overestimate the number of bins and it does not take into account data variability.

‘sturges’

$$n_h = \log_2(n) + 1$$

The number of bins is the base 2 log of `a.size`. This estimator assumes normality of data and is too conservative for larger, non-normal datasets. This is the default method in R’s `hist` method.

‘doane’

$$\begin{aligned} n_h &= 1 + \log_2(n) + \log_2 \left(1 + \frac{|g_1|}{\sigma_{g_1}} \right) \\ g_1 &= \text{mean} \left[\left(\frac{x - \mu}{\sigma} \right)^3 \right] \\ \sigma_{g_1} &= \sqrt{\frac{6(n-2)}{(n+1)(n+3)}} \end{aligned}$$

An improved version of Sturges’ formula that produces better estimates for non-normal datasets. This estimator attempts to account for the skew of the data.

‘sqrt’

$$n_h = \sqrt{n}$$

The simplest and fastest estimator. Only takes into account the data size.

Additionally, if the data is of integer dtype, then the binwidth will never be less than 1.

Examples

```
>>> import numpy as np
>>> arr = np.array([0, 0, 0, 1, 2, 3, 3, 4, 5])
>>> np.histogram_bin_edges(arr, bins='auto', range=(0, 1))
array([0. , 0.25, 0.5 , 0.75, 1.  ])
>>> np.histogram_bin_edges(arr, bins=2)
array([0. , 2.5, 5.  ])
```

For consistency with histogram, an array of pre-computed bins is passed through unmodified:

```
>>> np.histogram_bin_edges(arr, [1, 2])
array([1, 2])
```

This function allows one set of bins to be computed, and reused across multiple histograms:

```
>>> shared_bins = np.histogram_bin_edges(arr, bins='auto')
>>> shared_bins
array([0., 1., 2., 3., 4., 5.])
```

```
>>> group_id = np.array([0, 1, 1, 0, 1, 1, 0, 1, 1])
>>> hist_0, _ = np.histogram(arr[group_id == 0], bins=shared_bins)
>>> hist_1, _ = np.histogram(arr[group_id == 1], bins=shared_bins)
```

```
>>> hist_0; hist_1
array([1, 1, 0, 1, 0])
array([2, 0, 1, 1, 2])
```

Which gives more easily comparable results than using separate bins for each histogram:

```
>>> hist_0, bins_0 = np.histogram(arr[group_id == 0], bins='auto')
>>> hist_1, bins_1 = np.histogram(arr[group_id == 1], bins='auto')
>>> hist_0; hist_1
array([1, 1, 1])
array([2, 1, 1, 2])
>>> bins_0; bins_1
array([0., 1., 2., 3.])
array([0. , 1.25, 2.5 , 3.75, 5.  ])
```

`numpy.digitize(x, bins, right=False)`

Return the indices of the bins to which each value in input array belongs.

<i>right</i>	order of bins	returned index <i>i</i> satisfies
False	increasing	<code>bins[i-1] <= x < bins[i]</code>
True	increasing	<code>bins[i-1] < x <= bins[i]</code>
False	decreasing	<code>bins[i-1] > x >= bins[i]</code>
True	decreasing	<code>bins[i-1] >= x > bins[i]</code>

If values in x are beyond the bounds of $bins$, 0 or `len(bins)` is returned as appropriate.

Parameters

x

[array_like] Input array to be binned. Prior to NumPy 1.10.0, this array had to be 1-dimensional, but can now have any shape.

bins

[array_like] Array of bins. It has to be 1-dimensional and monotonic.

right

[bool, optional] Indicating whether the intervals include the right or the left bin edge. Default behavior is (`right==False`) indicating that the interval does not include the right edge. The left bin end is open in this case, i.e., $bins[i-1] \leq x < bins[i]$ is the default behavior for monotonically increasing bins.

Returns

indices

[ndarray of ints] Output array of indices, of same shape as x .

Raises

ValueError

If $bins$ is not monotonic.

TypeError

If the type of the input is complex.

See also:

[*bincount*](#), [*histogram*](#), [*unique*](#), [*searchsorted*](#)

Notes

If values in x are such that they fall outside the bin range, attempting to index $bins$ with the indices that [*digitize*](#) returns will result in an `IndexError`.

New in version 1.10.0.

[*numpy.digitize*](#) is implemented in terms of [*numpy.searchsorted*](#). This means that a binary search is used to bin the values, which scales much better for larger number of bins than the previous linear search. It also removes the requirement for the input array to be 1-dimensional.

For monotonically *increasing bins*, the following are equivalent:

```
np.digitize(x, bins, right=True)
np.searchsorted(bins, x, side='left')
```

Note that as the order of the arguments are reversed, the side must be too. The [*searchsorted*](#) call is marginally faster, as it does not do any monotonicity checks. Perhaps more importantly, it supports all dtypes.

Examples

```
>>> import numpy as np
>>> x = np.array([0.2, 6.4, 3.0, 1.6])
>>> bins = np.array([0.0, 1.0, 2.5, 4.0, 10.0])
>>> inds = np.digitize(x, bins)
>>> inds
array([1, 4, 3, 2])
>>> for n in range(x.size):
...     print(bins[inds[n]-1], "<=", x[n], "<", bins[inds[n]])
...
0.0 <= 0.2 < 1.0
4.0 <= 6.4 < 10.0
2.5 <= 3.0 < 4.0
1.0 <= 1.6 < 2.5
```

```
>>> x = np.array([1.2, 10.0, 12.4, 15.5, 20.1])
>>> bins = np.array([0, 5, 10, 15, 20])
>>> np.digitize(x,bins,right=True)
array([1, 2, 3, 4, 4])
>>> np.digitize(x,bins,right=False)
array([1, 3, 3, 4, 5])
```

1.4.18 Window functions

Various windows

<i>bartlett</i> (M)	Return the Bartlett window.
<i>blackman</i> (M)	Return the Blackman window.
<i>hamming</i> (M)	Return the Hamming window.
<i>hanning</i> (M)	Return the Hanning window.
<i>kaiser</i> (M, beta)	Return the Kaiser window.

`numpy.bartlett` (M)

Return the Bartlett window.

The Bartlett window is very similar to a triangular window, except that the end points are at zero. It is often used in signal processing for tapering a signal, without generating too much ripple in the frequency domain.

Parameters

M

[int] Number of points in the output window. If zero or less, an empty array is returned.

Returns

out

[array] The triangular window, with the maximum value normalized to one (the value one appears only if the number of samples is odd), with the first and last samples equal to zero.

See also:

blackman, *hamming*, *hanning*, *kaiser*

Notes

The Bartlett window is defined as

$$w(n) = \frac{2}{M-1} \left(\frac{M-1}{2} - \left| n - \frac{M-1}{2} \right| \right)$$

Most references to the Bartlett window come from the signal processing literature, where it is used as one of many windowing functions for smoothing values. Note that convolution with this window produces linear interpolation. It is also known as an apodization (which means “removing the foot”, i.e. smoothing discontinuities at the beginning and end of the sampled signal) or tapering function. The Fourier transform of the Bartlett window is the product of two sinc functions. Note the excellent discussion in Kanasewich [2].

References

[1], [2], [3], [4], [5]

Examples

```
>>> import numpy as np
>>> import matplotlib.pyplot as plt
>>> np.bartlett(12)
array([ 0.          ,  0.18181818,  0.36363636,  0.54545455,  0.72727273, # may vary
        0.90909091,  0.90909091,  0.72727273,  0.54545455,  0.36363636,
        0.18181818,  0.          ])
```

Plot the window and its frequency response (requires SciPy and matplotlib).

```
import matplotlib.pyplot as plt
from numpy.fft import fft, fftshift
window = np.bartlett(51)
plt.plot(window)
plt.title("Bartlett window")
plt.ylabel("Amplitude")
plt.xlabel("Sample")
plt.show()
```

```
plt.figure()
A = fft(window, 2048) / 25.5
mag = np.abs(fftshift(A))
freq = np.linspace(-0.5, 0.5, len(A))
with np.errstate(divide='ignore', invalid='ignore'):
    response = 20 * np.log10(mag)
response = np.clip(response, -100, 100)
plt.plot(freq, response)
plt.title("Frequency response of Bartlett window")
plt.ylabel("Magnitude [dB]")
plt.xlabel("Normalized frequency [cycles per sample]")
plt.axis('tight')
plt.show()
```

`numpy.blackman`(*M*)

Return the Blackman window.

The Blackman window is a taper formed by using the first three terms of a summation of cosines. It was designed to have close to the minimal leakage possible. It is close to optimal, only slightly worse than a Kaiser window.

Parameters**M**

[int] Number of points in the output window. If zero or less, an empty array is returned.

Returns**out**

[ndarray] The window, with the maximum value normalized to one (the value one appears only if the number of samples is odd).

See also:*bartlett*, *hamming*, *hanning*, *kaiser***Notes**

The Blackman window is defined as

$$w(n) = 0.42 - 0.5 \cos(2\pi n/M) + 0.08 \cos(4\pi n/M)$$

Most references to the Blackman window come from the signal processing literature, where it is used as one of many windowing functions for smoothing values. It is also known as an apodization (which means “removing the foot”, i.e. smoothing discontinuities at the beginning and end of the sampled signal) or tapering function. It is known as a “near optimal” tapering function, almost as good (by some measures) as the Kaiser window.

Examples

```
>>> import numpy as np
>>> import matplotlib.pyplot as plt
>>> np.blackman(12)
array([-1.38777878e-17,  3.26064346e-02,  1.59903635e-01, # may vary
        4.14397981e-01,  7.36045180e-01,  9.67046769e-01,
        9.67046769e-01,  7.36045180e-01,  4.14397981e-01,
        1.59903635e-01,  3.26064346e-02, -1.38777878e-17])
```

Plot the window and the frequency response.

```
import matplotlib.pyplot as plt
from numpy.fft import fft, fftshift
window = np.blackman(51)
plt.plot(window)
plt.title("Blackman window")
plt.ylabel("Amplitude")
plt.xlabel("Sample")
plt.show() # doctest: +SKIP
```

```
plt.figure()
A = fft(window, 2048) / 25.5
mag = np.abs(fftshift(A))
```

(continues on next page)

(continued from previous page)

```

freq = np.linspace(-0.5, 0.5, len(A))
with np.errstate(divide='ignore', invalid='ignore'):
    response = 20 * np.log10(mag)
response = np.clip(response, -100, 100)
plt.plot(freq, response)
plt.title("Frequency response of Blackman window")
plt.ylabel("Magnitude [dB]")
plt.xlabel("Normalized frequency [cycles per sample]")
plt.axis('tight')
plt.show()

```

`numpy.hamming` (*M*)

Return the Hamming window.

The Hamming window is a taper formed by using a weighted cosine.

Parameters**M**

[int] Number of points in the output window. If zero or less, an empty array is returned.

Returns**out**

[ndarray] The window, with the maximum value normalized to one (the value one appears only if the number of samples is odd).

See also:*bartlett*, *blackman*, *hanning*, *kaiser***Notes**

The Hamming window is defined as

$$w(n) = 0.54 - 0.46 \cos\left(\frac{2\pi n}{M-1}\right) \quad 0 \leq n \leq M-1$$

The Hamming was named for R. W. Hamming, an associate of J. W. Tukey and is described in Blackman and Tukey. It was recommended for smoothing the truncated autocovariance function in the time domain. Most references to the Hamming window come from the signal processing literature, where it is used as one of many windowing functions for smoothing values. It is also known as an apodization (which means “removing the foot”, i.e. smoothing discontinuities at the beginning and end of the sampled signal) or tapering function.

Examples

```
>>> import numpy as np
>>> np.hamming(12)
array([ 0.08      ,  0.15302337,  0.34890909,  0.60546483,  0.84123594, # may vary
        0.98136677,  0.98136677,  0.84123594,  0.60546483,  0.34890909,
        0.15302337,  0.08      ])
```

Plot the window and the frequency response.

```
import matplotlib.pyplot as plt
from numpy.fft import fft, fftshift
window = np.hamming(51)
plt.plot(window)
plt.title("Hamming window")
plt.ylabel("Amplitude")
plt.xlabel("Sample")
plt.show()
```

```
plt.figure()
A = fft(window, 2048) / 25.5
mag = np.abs(fftshift(A))
```

(continues on next page)

(continued from previous page)

```

freq = np.linspace(-0.5, 0.5, len(A))
response = 20 * np.log10(mag)
response = np.clip(response, -100, 100)
plt.plot(freq, response)
plt.title("Frequency response of Hamming window")
plt.ylabel("Magnitude [dB]")
plt.xlabel("Normalized frequency [cycles per sample]")
plt.axis('tight')
plt.show()

```

`numpy.hanning`(*M*)

Return the Hanning window.

The Hanning window is a taper formed by using a weighted cosine.

Parameters**M**

[int] Number of points in the output window. If zero or less, an empty array is returned.

Returns**out**[ndarray, shape(M,)] The window, with the maximum value normalized to one (the value one appears only if M is odd).**See also:***bartlett*, *blackman*, *hamming*, *kaiser***Notes**

The Hanning window is defined as

$$w(n) = 0.5 - 0.5 \cos\left(\frac{2\pi n}{M-1}\right) \quad 0 \leq n \leq M-1$$

The Hanning was named for Julius von Hann, an Austrian meteorologist. It is also known as the Cosine Bell. Some authors prefer that it be called a Hann window, to help avoid confusion with the very similar Hamming window.

Most references to the Hanning window come from the signal processing literature, where it is used as one of many windowing functions for smoothing values. It is also known as an apodization (which means “removing the foot”, i.e. smoothing discontinuities at the beginning and end of the sampled signal) or tapering function.

```
>>> import numpy as np
>>> np.hanning(12)
array([0.          , 0.07937323, 0.29229249, 0.57115742, 0.82743037,
        0.97974649, 0.97974649, 0.82743037, 0.57115742, 0.29229249,
        0.07937323, 0.          ])
```

Plot the window and its frequency response.

```
import matplotlib.pyplot as plt
from numpy.fft import fft, fftshift
window = np.hanning(51)
plt.plot(window)
plt.title("Hann window")
plt.ylabel("Amplitude")
plt.xlabel("Sample")
plt.show()
```

```
plt.figure()
A = fft(window, 2048) / 25.5
mag = np.abs(fftshift(A))
freq = np.linspace(-0.5, 0.5, len(A))
with np.errstate(divide='ignore', invalid='ignore'):
    response = 20 * np.log10(mag)
response = np.clip(response, -100, 100)
plt.plot(freq, response)
plt.title("Frequency response of the Hann window")
plt.ylabel("Magnitude [dB]")
plt.xlabel("Normalized frequency [cycles per sample]")
plt.axis('tight')
plt.show()
```

`numpy.kaiser` (M , β)

Return the Kaiser window.

The Kaiser window is a taper formed by using a Bessel function.

Parameters

M

[int] Number of points in the output window. If zero or less, an empty array is returned.

beta

[float] Shape parameter for window.

Returns

out

[array] The window, with the maximum value normalized to one (the value one appears only if the number of samples is odd).

See also:

bartlett, *blackman*, *hamming*, *hanning*

Notes

The Kaiser window is defined as

$$w(n) = I_0 \left(\beta \sqrt{1 - \frac{4n^2}{(M-1)^2}} \right) / I_0(\beta)$$

with

$$-\frac{M-1}{2} \leq n \leq \frac{M-1}{2},$$

where I_0 is the modified zeroth-order Bessel function.

The Kaiser was named for Jim Kaiser, who discovered a simple approximation to the DPSS window based on Bessel functions. The Kaiser window is a very good approximation to the Digital Prolate Spheroidal Sequence, or Slepian window, which is the transform which maximizes the energy in the main lobe of the window relative to total energy.

The Kaiser can approximate many other windows by varying the beta parameter.

beta	Window shape
0	Rectangular
5	Similar to a Hamming
6	Similar to a Hanning
8.6	Similar to a Blackman

A beta value of 14 is probably a good starting point. Note that as beta gets large, the window narrows, and so the number of samples needs to be large enough to sample the increasingly narrow spike, otherwise NaNs will get returned.

Most references to the Kaiser window come from the signal processing literature, where it is used as one of many windowing functions for smoothing values. It is also known as an apodization (which means “removing the foot”, i.e. smoothing discontinuities at the beginning and end of the sampled signal) or tapering function.

2.1 NumPy C-API

Beware of the man who won't be bothered with details.

— *William Feather, Sr.*

The truth is out there.

— *Chris Carter, The X Files*

NumPy provides a C-API to enable users to extend the system and get access to the array object for use in other routines. The best way to truly understand the C-API is to read the source code. If you are unfamiliar with (C) source code, however, this can be a daunting experience at first. Be assured that the task becomes easier with practice, and you may be surprised at how simple the C-code can be to understand. Even if you don't think you can write C-code from scratch, it is much easier to understand and modify already-written source code than create it *de novo*.

Python extensions are especially straightforward to understand because they all have a very similar structure. Admittedly, NumPy is not a trivial extension to Python, and may take a little more snooping to grasp. This is especially true because of the code-generation techniques, which simplify maintenance of very similar code, but can make the code a little less readable to beginners. Still, with a little persistence, the code can be opened to your understanding. It is my hope, that this guide to the C-API can assist in the process of becoming familiar with the compiled-level work that can be done with NumPy in order to squeeze that last bit of necessary speed out of your code.

2.1.1 Python types and C-structures

Several new types are defined in the C-code. Most of these are accessible from Python, but a few are not exposed due to their limited use. Every new Python type has an associated `PyObject*` with an internal structure that includes a pointer to a “method table” that defines how the new object behaves in Python. When you receive a Python object into C code, you always get a pointer to a `PyObject` structure. Because a `PyObject` structure is very generic and defines only `PyObject_HEAD`, by itself it is not very interesting. However, different objects contain more details after the `PyObject_HEAD` (but you have to cast to the correct type to access them — or use accessor functions or macros).

New Python types defined

Python types are the functional equivalent in C of classes in Python. By constructing a new Python type you make available a new object for Python. The ndarray object is an example of a new type defined in C. New types are defined in C by two basic steps:

1. creating a C-structure (usually named `Py{Name}Object`) that is binary-compatible with the `PyObject` structure itself but holds the additional information needed for that particular object;
2. populating the `PyTypeObject` table (pointed to by the `ob_type` member of the `PyObject` structure) with pointers to functions that implement the desired behavior for the type.

Instead of special method names which define behavior for Python classes, there are “function tables” which point to functions that implement the desired results. The `PyTypeObject` itself is dynamic which allows C types that can be “sub-typed” from other C-types in C, and sub-classed in Python. The children types inherit the attributes and methods from their parent(s).

There are two major new types: the ndarray (`PyArray_Type`) and the ufunc (`PyUFunc_Type`). Additional types play a supportive role: the `PyArrayIter_Type`, the `PyArrayMultiIter_Type`, and the `PyArrayDescr_Type` . The `PyArrayIter_Type` is the type for a flat iterator for an ndarray (the object that is returned when getting the flat attribute). The `PyArrayMultiIter_Type` is the type of the object returned when calling `broadcast`. It handles iteration and broadcasting over a collection of nested sequences. Also, the `PyArrayDescr_Type` is the data-type-descriptor type whose instances describe the data and `PyArray_DTypeMeta` is the metaclass for data-type descriptors. There are also new scalar-array types which are new Python scalars corresponding to each of the fundamental data types available for arrays. Additional types are placeholders that allow the array scalars to fit into a hierarchy of actual Python types. Finally, the `PyArray_DTypeMeta` instances corresponding to the NumPy built-in data types are also publicly visible.

PyArray_Type and PyArrayObject

PyTypeObject `PyArray_Type`

The Python type of the ndarray is `PyArray_Type`. In C, every ndarray is a pointer to a `PyArrayObject` structure. The `ob_type` member of this structure contains a pointer to the `PyArray_Type` typeobject.

type `PyArrayObject`

type `NPY_AO`

The `PyArrayObject` C-structure contains all of the required information for an array. All instances of an ndarray (and its subclasses) will have this structure. For future compatibility, these structure members should normally be accessed using the provided macros. If you need a shorter name, then you can make use of `NPY_AO` (deprecated) which is defined to be equivalent to `PyArrayObject`. Direct access to the struct fields are deprecated. Use the `PyArray_*` (arr) form instead. As of NumPy 1.20, the size of this struct is not considered part of the NumPy ABI (see note at the end of the member list).

```
typedef struct PyArrayObject {
    PyObject_HEAD
    char *data;
    int nd;
    npy_intp *dimensions;
    npy_intp *strides;
    PyObject *base;
    PyArray_Descr *descr;
    int flags;
    PyObject *weakreflist;
    /* version dependent private members */
} PyArrayObject;
```

`PyObject_HEAD`

This is needed by all Python objects. It consists of (at least) a reference count member (`ob_refcnt`) and a pointer to the typeobject (`ob_type`). (Other elements may also be present if Python was compiled with special options see `Include/object.h` in the Python source tree for more information). The `ob_type` member points to a Python type object.

`char *data`

Accessible via `PyArray_DATA`, this data member is a pointer to the first element of the array. This pointer can (and normally should) be recast to the data type of the array.

`int nd`

An integer providing the number of dimensions for this array. When `nd` is 0, the array is sometimes called a rank-0 array. Such arrays have undefined dimensions and strides and cannot be accessed. Macro `PyArray_NDIM` defined in `ndarraytypes.h` points to this data member. `NPY_MAXDIMS` is defined as a compile time constant limiting the number of dimensions. This number is 64 since NumPy 2 and was 32 before. However, we may wish to remove this limitations in the future so that it is best to explicitly check dimensionality for code that relies on such an upper bound.

`numpy_intp *dimensions`

An array of integers providing the shape in each dimension as long as `nd` $\geq$ 1. The integer is always large enough to hold a pointer on the platform, so the dimension size is only limited by memory. `PyArray_DIMS` is the macro associated with this data member.

`numpy_intp *strides`

An array of integers providing for each dimension the number of bytes that must be skipped to get to the next element in that dimension. Associated with macro `PyArray_STRIDES`.

`PyObject *base`

Pointed to by `PyArray_BASE`, this member is used to hold a pointer to another Python object that is related to this array. There are two use cases:

- If this array does not own its own memory, then `base` points to the Python object that owns it (perhaps another array object)
- If this array has the `NPY_ARRAY_WRITEBACKIFCOPY` flag set, then this array is a working copy of a “misbehaved” array.

When `PyArray_ResolveWritebackIfCopy` is called, the array pointed to by `base` will be updated with the contents of this array.

`PyArray_Descr *descr`

A pointer to a data-type descriptor object (see below). The data-type descriptor object is an instance of a new built-in type which allows a generic description of memory. There is a descriptor structure for each data type supported. This descriptor structure contains useful information about the type as well as a pointer to a table of function pointers to implement specific functionality. As the name suggests, it is associated with the macro `PyArray_DESCR`.

`int flags`

Pointed to by the macro `PyArray_FLAGS`, this data member represents the flags indicating how the memory pointed to by `data` is to be interpreted. Possible flags are `NPY_ARRAY_C_CONTIGUOUS`, `NPY_ARRAY_F_CONTIGUOUS`, `NPY_ARRAY_OWNDATA`, `NPY_ARRAY_ALIGNED`, `NPY_ARRAY_WRITEABLE`, `NPY_ARRAY_WRITEBACKIFCOPY`.

`PyObject *weakreflist`

This member allows array objects to have weak references (using the `weakref` module).

Note: Further members are considered private and version dependent. If the size of the struct is important for your code, special care must be taken. A possible use-case when this is relevant is subclassing in C. If your code relies on `sizeof(PyArrayObject)` to be constant, you must add the following check at import time:

```
if (sizeof(PyArrayObject) < PyArray_Type.tp_basicsize) {
    PyErr_SetString(PyExc_ImportError,
        "Binary incompatibility with NumPy, must recompile/update X.");
    return NULL;
}
```

To ensure that your code does not have to be compiled for a specific NumPy version, you may add a constant, leaving room for changes in NumPy. A solution guaranteed to be compatible with any future NumPy version requires the use of a runtime calculate offset and allocation size.

The `PyArray_Type` typeobject implements many of the features of Python objects including the `tp_as_number`, `tp_as_sequence`, `tp_as_mapping`, and `tp_as_buffer` interfaces. The rich comparison is also used along with new-style attribute lookup for member (`tp_members`) and properties (`tp_getset`). The `PyArray_Type` can also be sub-typed.

Tip: The `tp_as_number` methods use a generic approach to call whatever function has been registered for handling the operation. When the `_multiarray_umath` module is imported, it sets the numeric operations for all arrays to the corresponding ufuncs. This choice can be changed with `PyUFunc_ReplaceLoopBySignature`.

PyGenericArrType_Type

PyTypeObject PyGenericArrType_Type

The `PyGenericArrType_Type` is the PyTypeObject definition which create the `numpy.generic` python type.

PyArrayDescr_Type and PyArray_Descr

PyTypeObject PyArrayDescr_Type

The `PyArrayDescr_Type` is the built-in type of the data-type-descriptor objects used to describe how the bytes comprising the array are to be interpreted. There are 21 statically-defined `PyArray_Descr` objects for the built-in data-types. While these participate in reference counting, their reference count should never reach zero. There is also a dynamic table of user-defined `PyArray_Descr` objects that is also maintained. Once a data-type-descriptor object is “registered” it should never be deallocated either. The function `PyArray_DescrFromType` (...) can be used to retrieve a `PyArray_Descr` object from an enumerated type-number (either built-in or user-defined).

type PyArray_DescrProto

Identical structure to `PyArray_Descr`. This struct is used for static definition of a prototype for registering a new legacy DType by `PyArray_RegisterDataType`.

See the note in `PyArray_RegisterDataType` for details.

type PyArray_Descr

The `PyArray_Descr` structure lies at the heart of the `PyArrayDescr_Type`. While it is described here for completeness, it should be considered internal to NumPy and manipulated via `PyArrayDescr_*` or `PyDataType_*` functions and macros. The size of this structure is subject to change across versions of NumPy. To ensure compatibility:

- Never declare a non-pointer instance of the struct

- Never perform pointer arithmetic
- Never use `sizeof (PyArray_Descr)`

It has the following structure:

```
typedef struct {
    PyObject_HEAD
    PyTypeObject *typeobj;
    char kind;
    char type;
    char byteorder;
    char _former_flags; // unused field
    int type_num;
    /*
     * Definitions after this one must be accessed through accessor
     * functions (see below) when compiling with NumPy 1.x support.
     */
    npy_uint64 flags;
    npy_intp elsize;
    npy_intp alignment;
    NpyAuxData *c_metadata;
    npy_hash_t hash;
    void *reserved_null[2]; // unused field, must be NULLed.
} PyArray_Descr;
```

Some dtypes have additional members which are accessible through `PyDataType_NAMES`, `PyDataType_FIELDS`, `PyDataType_SUBARRAY`, and in some cases (times) `PyDataType_C_METADATA`.

PyTypeObject *typeobj

Pointer to a typeobject that is the corresponding Python type for the elements of this array. For the builtin types, this points to the corresponding array scalar. For user-defined types, this should point to a user-defined typeobject. This typeobject can either inherit from array scalars or not. If it does not inherit from array scalars, then the `NPY_USE_GETITEM` and `NPY_USE_SETITEM` flags should be set in the `flags` member.

char kind

A character code indicating the kind of array (using the array interface typestring notation). A 'b' represents Boolean, a 'i' represents signed integer, a 'u' represents unsigned integer, 'f' represents floating point, 'c' represents complex floating point, 'S' represents 8-bit zero-terminated bytes, 'U' represents 32-bit/character unicode string, and 'V' represents arbitrary.

char type

A traditional character code indicating the data type.

char byteorder

A character indicating the byte-order: '>' (big-endian), '<' (little-endian), '=' (native), '|' (irrelevant, ignore). All builtin data- types have byteorder '='.

npy_uint64 flags

A data-type bit-flag that determines if the data-type exhibits object- array like behavior. Each bit in this member is a flag which are named as:

- `NPY_ITEM_REFCOUNT`
- `NPY_ITEM_HASOBJECT`
- `NPY_LIST_PICKLE`
- `NPY_ITEM_IS_POINTER`
- `NPY_NEEDS_INIT`

- *NPY_NEEDS_PYAPI*
- *NPY_USE_GETITEM*
- *NPY_USE_SETITEM*
- *NPY_FROM_FIELDS*
- *NPY_OBJECT_DTYPE_FLAGS*

int `type_num`

A number that uniquely identifies the data type. For new data-types, this number is assigned when the data-type is registered.

***numpy_intp* `elsize`**

For data types that are always the same size (such as long), this holds the size of the data type. For flexible data types where different arrays can have a different elementsize, this should be 0.

See *PyDataType_ELSIZE* and *PyDataType_SET_ELSIZE* for a way to access this field in a NumPy 1.x compatible way.

***numpy_intp* `alignment`**

A number providing alignment information for this data type. Specifically, it shows how far from the start of a 2-element structure (whose first element is a `char`), the compiler places an item of this type: `offsetof(struct {char c; type v;}, v)`

See *PyDataType_ALIGNMENT* for a way to access this field in a NumPy 1.x compatible way.

PyObject* `metadata`

Metadata about this dtype.

***NpyAuxData** `c_metadata`**

Metadata specific to the C implementation of the particular dtype. Added for NumPy 1.7.0.

type `numpy_hash_t`***numpy_hash_t** `hash`**

Used for caching hash values.

`NPY_ITEM_REFCOUNT`

Indicates that items of this data-type must be reference counted (using *Py_INCREF* and *Py_DECREF*).

`NPY_ITEM_HASOBJECT`

Same as *NPY_ITEM_REFCOUNT*.

`NPY_LIST_PICKLE`

Indicates arrays of this data-type must be converted to a list before pickling.

`NPY_ITEM_IS_POINTER`

Indicates the item is a pointer to some other data-type

`NPY_NEEDS_INIT`

Indicates memory for this data-type must be initialized (set to 0) on creation.

`NPY_NEEDS_PYAPI`

Indicates this data-type requires the Python C-API during access (so don't give up the GIL if array access is going to be needed).

NPY_USE_GETITEM

On array access use the `f->getitem` function pointer instead of the standard conversion to an array scalar. Must use if you don't define an array scalar to go along with the data-type.

NPY_USE_SETITEM

When creating a 0-d array from an array scalar use `f->setitem` instead of the standard copy from an array scalar. Must use if you don't define an array scalar to go along with the data-type.

NPY_FROM_FIELDS

The bits that are inherited for the parent data-type if these bits are set in any field of the data-type. Currently (`NPY_NEEDS_INIT` | `NPY_LIST_PICKLE` | `NPY_ITEM_REFCOUNT` | `NPY_NEEDS_PYAPI`).

NPY_OBJECT_DTYPE_FLAGS

Bits set for the object data-type: (`NPY_LIST_PICKLE` | `NPY_USE_GETITEM` | `NPY_ITEM_IS_POINTER` | `NPY_ITEM_REFCOUNT` | `NPY_NEEDS_INIT` | `NPY_NEEDS_PYAPI`).

int **PyDataType_FLAGCHK** (*PyArray_Descr* *dtype, int flags)

Return true if all the given flags are set for the data-type object.

int **PyDataType_REFCHK** (*PyArray_Descr* *dtype)

Equivalent to `PyDataType_FLAGCHK (dtype, NPY_ITEM_REFCOUNT)`.

PyArray_ArrFuncs

PyArray_ArrFuncs ***PyDataType_GetArrFuncs** (*PyArray_Descr* *dtype)

Fetch the legacy *PyArray_ArrFuncs* of the datatype (cannot fail).

New in version NumPy: 2.0 This function was added in a backwards compatible and backportable way in NumPy 2.0 (see `numpy_2_compat.h`). Any code that previously accessed the `->f` slot of the *PyArray_Descr*, must now use this function and backport it to compile with 1.x. (The `numpy_2_compat.h` header can be vendored for this purpose.)

type PyArray_ArrFuncs

Functions implementing internal features. Not all of these function pointers must be defined for a given type. The required members are `nonzero`, `copyswap`, `copyswapn`, `setitem`, `getitem`, and `cast`. These are assumed to be non- NULL and NULL entries will cause a program crash. The other functions may be NULL which will just mean reduced functionality for that data-type. (Also, the `nonzero` function will be filled in with a default function if it is NULL when you register a user-defined data-type).

```
typedef struct {
    PyArray_VectorUnaryFunc *cast[NPY_NTYPES_LEGACY];
    PyArray_GetItemFunc *getitem;
    PyArray_SetItemFunc *setitem;
    PyArray_CopySwapNFunc *copyswapn;
    PyArray_CopySwapFunc *copyswap;
    PyArray_CompareFunc *compare;
    PyArray_ArgFunc *argmax;
    PyArray_DotFunc *dotfunc;
    PyArray_ScanFunc *scanfunc;
    PyArray_FromStrFunc *fromstr;
    PyArray_NonzeroFunc *nonzero;
    PyArray_FillFunc *fill;
    PyArray_FillWithScalarFunc *fillwithscalar;
    PyArray_SortFunc *sort[NPY_NSORTS];
    PyArray_ArgSortFunc *argsort[NPY_NSORTS];
    PyObject *castdict;
    PyArray_ScalarKindFunc *scalarkind;
```

(continues on next page)

(continued from previous page)

```

    int **cancastscalarkindto;
    int *cancastto;
    void *_unused1;
    void *_unused2;
    void *_unused3;
    PyArray_ArgFunc *argmin;
} PyArray_ArrFuncs;

```

The concept of a behaved segment is used in the description of the function pointers. A behaved segment is one that is aligned and in native machine byte-order for the data-type. The `nonzero`, `copyswap`, `copyswapn`, `getitem`, and `setitem` functions can (and must) deal with mis-behaved arrays. The other functions require behaved memory segments.

Note: The functions are largely legacy API, however, some are still used. As of NumPy 2.x they are only available via `PyDataType_GetArrFuncs` (see the function for more details). Before using any function defined in the struct you should check whether it is `NULL`. In general, the functions `getitem`, `setitem`, `copyswap`, and `copyswapn` can be expected to be defined, but all functions are expected to be replaced with newer API. For example, `PyArray_Pack` is a more powerful version of `setitem` that for example correctly deals with casts.

void **cast** (void *from, void *to, *numpy_intp* n, void *fromarr, void *toarr)

An array of function pointers to cast from the current type to all of the other builtin types. Each function casts a contiguous, aligned, and notswapped buffer pointed at by *from* to a contiguous, aligned, and notswapped buffer pointed at by *to*. The number of items to cast is given by *n*, and the arguments *fromarr* and *toarr* are interpreted as `PyArrayObjects` for flexible arrays to get itemsize information.

PyObject ***getitem** (void *data, void *arr)

A pointer to a function that returns a standard Python object from a single element of the array object *arr* pointed to by *data*. This function must be able to deal with “misbehaved” (misaligned and/or swapped) arrays correctly.

int **setitem** (*PyObject* *item, void *data, void *arr)

A pointer to a function that sets the Python object *item* into the array, *arr*, at the position pointed to by *data*. This function deals with “misbehaved” arrays. If successful, a zero is returned, otherwise, a negative one is returned (and a Python error set).

void **copyswapn** (void *dest, *numpy_intp* dstride, void *src, *numpy_intp* sstride, *numpy_intp* n, int swap, void *arr)

void **copyswap** (void *dest, void *src, int swap, void *arr)

These members are both pointers to functions to copy data from *src* to *dest* and *swap* if indicated. The value of *arr* is only used for flexible (`NPY_STRING`, `NPY_UNICODE`, and `NPY_VOID`) arrays (and is obtained from `arr->descr->elsize`). The second function copies a single value, while the first loops over *n* values with the provided strides. These functions can deal with misbehaved *src* data. If *src* is `NULL` then no copy is performed. If *swap* is 0, then no byteswapping occurs. It is assumed that *dest* and *src* do not overlap. If they overlap, then use `memmove (...)` first followed by `copyswap (n)` with `NULL` valued *src*.

int **compare** (const void *d1, const void *d2, void *arr)

A pointer to a function that compares two elements of the array, *arr*, pointed to by *d1* and *d2*. This function requires behaved (aligned and not swapped) arrays. The return value is 1 if `*d1 > *d2`, 0 if `*d1 == *d2`, and -1 if `*d1 < *d2`. The array object *arr* is used to retrieve itemsize and field information for flexible arrays.

int **argmax** (void *data, *numpy_intp* n, *numpy_intp* *max_ind, void *arr)

A pointer to a function that retrieves the index of the largest of *n* elements in *arr* beginning at the element

pointed to by `data`. This function requires that the memory segment be contiguous and behaved. The return value is always 0. The index of the largest element is returned in `max_ind`.

void **dotfunc** (void *ip1, *numpy_intp* is1, void *ip2, *numpy_intp* is2, void *op, *numpy_intp* n, void *arr)

A pointer to a function that multiplies two `n`-length sequences together, adds them, and places the result in element pointed to by `op` of `arr`. The start of the two sequences are pointed to by `ip1` and `ip2`. To get to the next element in each sequence requires a jump of `is1` and `is2 bytes`, respectively. This function requires behaved (though not necessarily contiguous) memory.

int **scanfunc** (FILE *fd, void *ip, void *arr)

A pointer to a function that scans (scanf style) one element of the corresponding type from the file descriptor `fd` into the array memory pointed to by `ip`. The array is assumed to be behaved. The last argument `arr` is the array to be scanned into. Returns number of receiving arguments successfully assigned (which may be zero in case a matching failure occurred before the first receiving argument was assigned), or EOF if input failure occurs before the first receiving argument was assigned. This function should be called without holding the Python GIL, and has to grab it for error reporting.

int **fromstr** (char *str, void *ip, char **endptr, void *arr)

A pointer to a function that converts the string pointed to by `str` to one element of the corresponding type and places it in the memory location pointed to by `ip`. After the conversion is completed, `*endptr` points to the rest of the string. The last argument `arr` is the array into which `ip` points (needed for variable-size data- types). Returns 0 on success or -1 on failure. Requires a behaved array. This function should be called without holding the Python GIL, and has to grab it for error reporting.

numpy_bool **nonzero** (void *data, void *arr)

A pointer to a function that returns TRUE if the item of `arr` pointed to by `data` is nonzero. This function can deal with misbehaved arrays.

void **fill** (void *data, *numpy_intp* length, void *arr)

A pointer to a function that fills a contiguous array of given length with data. The first two elements of the array must already be filled- in. From these two values, a delta will be computed and the values from item 3 to the end will be computed by repeatedly adding this computed delta. The data buffer must be well-behaved.

void **fillwithscalar** (void *buffer, *numpy_intp* length, void *value, void *arr)

A pointer to a function that fills a contiguous buffer of the given length with a single scalar value whose address is given. The final argument is the array which is needed to get the itemsize for variable-length arrays.

int **sort** (void *start, *numpy_intp* length, void *arr)

An array of function pointers to a particular sorting algorithms. A particular sorting algorithm is obtained using a key (so far `NPY_QUICKSORT`, `NPY_HEAPSORT`, and `NPY_MERGESORT` are defined). These sorts are done in-place assuming contiguous and aligned data.

int **argsort** (void *start, *numpy_intp* *result, *numpy_intp* length, void *arr)

An array of function pointers to sorting algorithms for this data type. The same sorting algorithms as for `sort` are available. The indices producing the sort are returned in `result` (which must be initialized with indices 0 to `length-1` inclusive).

PyObject ***castdict**

Either NULL or a dictionary containing low-level casting functions for user- defined data-types. Each function is wrapped in a `PyCapsule*` and keyed by the data-type number.

NPY_SCALARKIND **scalarkind** (*PyArrayObject* *arr)

A function to determine how scalars of this type should be interpreted. The argument is NULL or a 0-dimensional array containing the data (if that is needed to determine the kind of scalar). The return value must be of type `NPY_SCALARKIND`.

int ****cancastscalarkindto**

Either NULL or an array of `NPY_NSCALARKINDS` pointers. These pointers should each be either NULL or a pointer to an array of integers (terminated by `NPY_NOTYPE`) indicating data-types that a scalar of this data-type of the specified kind can be cast to safely (this usually means without losing precision).

int ***cancastto**

Either NULL or an array of integers (terminated by `NPY_NOTYPE`) indicated data-types that this data-type can be cast to safely (this usually means without losing precision).

int **argmin** (void *data, *numpy_intp* n, *numpy_intp* *min_ind, void *arr)

A pointer to a function that retrieves the index of the smallest of n elements in arr beginning at the element pointed to by data. This function requires that the memory segment be contiguous and behaved. The return value is always 0. The index of the smallest element is returned in min_ind.

PyArrayMethod_Context and PyArrayMethod_Spec

type **PyArrayMethodObject_tag**

An opaque struct used to represent the method “self” in ArrayMethod loops.

type **PyArrayMethod_Context**

A struct that is passed in to ArrayMethod loops to provide context for the runtime usage of the loop.

```
typedef struct {
    PyObject *caller;
    struct PyArrayMethodObject_tag *method;
    PyArray_Descr *const *descriptors;
    void *parameters;
} PyArrayMethod_Context
```

PyObject ***caller**

The caller, which is typically the ufunc that called the loop. May be NULL when a call is not from a ufunc (e.g. casts).

struct *PyArrayMethodObject_tag* ***method**

The method “self”. Currently this object is an opaque pointer.

PyArray_Descr ****descriptors**

An array of descriptors for the ufunc loop, filled in by `resolve_descriptors`. The length of the array is `nin + nout`.

void ***parameters**

A pointer to a structure containing any runtime parameters needed by the loop. This is NULL if no parameters are needed. The type of the struct is specific to the registered function.

Changed in version NumPy: 2.4 The *parameters* member was added in NumPy 2.4.

type **PyArrayMethod_Spec**

A struct used to register an ArrayMethod with NumPy. We use the slots mechanism used by the Python limited API. See below for the slot definitions.

```
typedef struct {
    const char *name;
    int nin, nout;
    NPY_CASTING casting;
    NPY_ARRAYMETHOD_FLAGS flags;
    PyArray_DTypeMeta **dtypes;
```

(continues on next page)

(continued from previous page)

```
PyType_Slot *slots;
} PyArrayMethod_Spec;
```

const char ***name**

The name of the loop.

int **nin**

The number of input operands

int **nout**

The number of output operands.

NPY_CASTING **casting**

Used to indicate how minimally permissive a casting operation should be. For example, if a cast operation might in some circumstances be safe, but in others unsafe, then `NPY_UNSAFE_CASTING` should be set. Not used for ufunc loops but must still be set.

NPY_ARRAYMETHOD_FLAGS **flags**

The flags set for the method.

PyArray_DTypeMeta ****dtypes**

The DTypes for the loop. Must be `nin + nout` in length.

PyType_Slot ***slots**

An array of slots for the method. Slot IDs must be one of the values below.

PyArray_DTypeMeta and PyArrayDTypeMeta_Spec

PyTypeObject **PyArrayDTypeMeta_Type**

The python type object corresponding to *PyArray_DTypeMeta*.

type **PyArray_DTypeMeta**

A largely opaque struct representing DType classes. Each instance defines a metaclass for a single NumPy data type. Data types can either be non-parametric or parametric. For non-parametric types, the DType class has a one-to-one correspondence with the descriptor instance created from the DType class. Parametric types can correspond to many different dtype instances depending on the chosen parameters. This type is available in the public `numpy/dtype_api.h` header. Currently use of this struct is not supported in the limited CPython API, so if `Py_LIMITED_API` is set, this type is a typedef for `PyTypeObject`.

```
typedef struct {
    PyHeapTypeObject super;
    PyArray_Descr *singleton;
    int type_num;
    PyTypeObject *scalar_type;
    npy_uint64 flags;
    void *dt_slots;
    void *reserved[3];
} PyArray_DTypeMeta
```

PyHeapTypeObject **super**

The superclass, providing hooks into the python object API. Set members of this struct to fill in the functions implementing the PyTypeObject API (e.g. `tp_new`).

PyArray_Descr ***singleton**

A descriptor instance suitable for use as a singleton descriptor for the data type. This is useful for non-parametric types representing simple plain old data type where there is only one logical descriptor instance for all data of the type. Can be NULL if a singleton instance is not appropriate.

int **type_num**

Corresponds to the type number for legacy data types. Data types defined outside of NumPy and possibly future data types shipped with NumPy will have `type_num` set to -1, so this should not be relied on to discriminate between data types.

PyTypeObject ***scalar_type**

The type of scalar instances for this data type.

numpy_uint64 **flags**

Flags can be set to indicate to NumPy that this data type has optional behavior. See [Flags](#) for a listing of allowed flag values.

void ***dt_slots**

An opaque pointer to a private struct containing implementations of functions in the DType API. This is filled in from the `slots` member of the `PyArrayDTypeMeta_Spec` instance used to initialize the DType.

type **PyArrayDTypeMeta_Spec**

A struct used to initialize a new DType with the `PyArrayInitDTypeMeta_FromSpec` function.

```
typedef struct {
    PyTypeObject *typeobj;
    int flags;
    PyArrayMethod_Spec **casts;
    PyType_Slot *slots;
    PyTypeObject *baseclass;
}
```

PyTypeObject ***typeobj**

Either NULL or the type of the python scalar associated with the DType. Scalar indexing into an array returns an item with this type.

int **flags**

Static flags for the DType class, indicating whether the DType is parametric, abstract, or represents numeric data. The latter is optional but is useful to set to indicate to downstream code if the DType represents data that are numbers (ints, floats, or other numeric data type) or something else (e.g. a string, unit, or date).

PyArrayMethod_Spec ****casts**;

A NULL-terminated array of ArrayMethod specifications for casts defined by the DType.

PyType_Slot ***slots**;

A NULL-terminated array of slot specifications for implementations of functions in the DType API. Slot IDs must be one of the DType slot IDs enumerated in [Slot IDs and API Function Typedefs](#).

Exposed DTypes classes (PyArray_DTypeMeta objects)

For use with promoters, NumPy exposes a number of Dtypes following the pattern `PyArray_<Name>DType` corresponding to those found in `np.dtypes`.

Additionally, the three DTypes, `PyArray_PyLongDType`, `PyArray_PyFloatDType`, `PyArray_PyComplexDType` correspond to the Python scalar values. These cannot be used in all places, but do allow for example the common dtype operation and implementing promotion with them may be necessary.

Further, the following abstract DTypes are defined which cover both the builtin NumPy ones and the python ones, and users can in principle subclass from them (this does not inherit any DType specific functionality): `* PyArray_IntAbstractDType * PyArray_FloatAbstractDType * PyArray_ComplexAbstractDType`

Warning: As of NumPy 2.0, the *only* valid use for these DTypes is registering a promoter conveniently to e.g. match “any integers” (and subclass checks). Because of this, they are not exposed to Python.

PyUFunc_Type and PyUFuncObject

PyTypeObject PyUFunc_Type

The ufunc object is implemented by creation of the `PyUFunc_Type`. It is a very simple type that implements only basic getattribute behavior, printing behavior, and has call behavior which allows these objects to act like functions. The basic idea behind the ufunc is to hold a reference to fast 1-dimensional (vector) loops for each data type that supports the operation. These one-dimensional loops all have the same signature and are the key to creating a new ufunc. They are called by the generic looping code as appropriate to implement the N-dimensional function. There are also some generic 1-d loops defined for floating and complexfloating arrays that allow you to define a ufunc using a single scalar function (e.g. `atanh`).

type PyUFuncObject

The core of the ufunc is the `PyUFuncObject` which contains all the information needed to call the underlying C-code loops that perform the actual work. While it is described here for completeness, it should be considered internal to NumPy and manipulated via `PyUFunc_*` functions. The size of this structure is subject to change across versions of NumPy. To ensure compatibility:

- Never declare a non-pointer instance of the struct
- Never perform pointer arithmetic
- Never use `sizeof(PyUFuncObject)`

It has the following structure:

```
typedef struct {
    PyObject_HEAD
    int nin;
    int nout;
    int nargs;
    int identity;
    PyUFuncGenericFunction *functions;
    void **data;
    int ntypes;
    int _ufunc_flags;
    const char *name;
    char *types;
    const char *doc;
    void *ptr;
    PyObject *obj;
    PyObject *userloops;
    int core_enabled;
    int core_num_dim_ix;
    int *core_num_dims;
    int *core_dim_ixs;
    int *core_offsets;
    char *core_signature;
    PyUFunc_TypeResolutionFunc *type_resolver;
    void *reserved2;
    void *reserved3;
    npy_uint32 *op_flags;
    npy_uint32 *iter_flags;
    /* new in API version 0x0000000D */
    npy_intp *core_dim_sizes;
```

(continues on next page)

(continued from previous page)

```

    npy_uint32 *core_dim_flags;
    PyObject *identity_value;
    /* Further private slots (size depends on the NumPy version) */
} PyUFuncObject;

```

int `nin`

The number of input arguments.

int `nout`

The number of output arguments.

int `nargs`The total number of arguments (`nin + nout`). This must be less than `NPY_MAXARGS`.**int `identity`**

Either `PyUFunc_One`, `PyUFunc_Zero`, `PyUFunc_MinusOne`, `PyUFunc_None`, `PyUFunc_ReorderableNone`, or `PyUFunc_IdentityValue` to indicate the identity for this operation. It is only used for a reduce-like call on an empty array.

void `functions` (`char **args`, `npy_intp *dims`, `npy_intp *steps`, `void *extradata`)

An array of function pointers — one for each data type supported by the ufunc. This is the vector loop that is called to implement the underlying function `dims[0]` times. The first argument, `args`, is an array of `nargs` pointers to behaved memory. Pointers to the data for the input arguments are first, followed by the pointers to the data for the output arguments. How many bytes must be skipped to get to the next element in the sequence is specified by the corresponding entry in the `steps` array. The last argument allows the loop to receive extra information. This is commonly used so that a single, generic vector loop can be used for multiple functions. In this case, the actual scalar function to call is passed in as `extradata`. The size of this function pointer array is `ntypes`.

void `**data`

Extra data to be passed to the 1-d vector loops or `NULL` if no extra-data is needed. This C-array must be the same size (*i.e.* `ntypes`) as the functions array. `NULL` is used if `extra_data` is not needed. Several C-API calls for UFuncs are just 1-d vector loops that make use of this extra data to receive a pointer to the actual function to call.

int `ntypes`

The number of supported data types for the ufunc. This number specifies how many different 1-d loops (of the builtin data types) are available.

char `*name`

A string name for the ufunc. This is used dynamically to build the `__doc__` attribute of ufuncs.

char `*types`

An array of `nargs × ntypes` 8-bit `type_numbers` which contains the type signature for the function for each of the supported (builtin) data types. For each of the `ntypes` functions, the corresponding set of type numbers in this array shows how the `args` argument should be interpreted in the 1-d vector loop. These type numbers do not have to be the same type and mixed-type ufuncs are supported.

char `*doc`

Documentation for the ufunc. Should not contain the function signature as this is generated dynamically when `__doc__` is retrieved.

void `*ptr`

Any dynamically allocated memory. Currently, this is used for dynamic ufuncs created from a python function to store room for the types, data, and name members.

PyObject *obj

For ufuncs dynamically created from python functions, this member holds a reference to the underlying Python function.

PyObject *userloops

A dictionary of user-defined 1-d vector loops (stored as CObject ptrs) for user-defined types. A loop may be registered by the user for any user-defined type. It is retrieved by type number. User defined type numbers are always larger than `NPY_USERDEF`.

int core_enabled

0 for scalar ufuncs; 1 for generalized ufuncs

int core_num_dim_ix

Number of distinct core dimension names in the signature

int *core_num_dims

Number of core dimensions of each argument

int *core_dim_ixs

Dimension indices in a flattened form; indices of argument `k` are stored in `core_dim_ixs[core_offsets[k] : core_offsets[k] + core_numdims[k]]`

int *core_offsets

Position of 1st core dimension of each argument in `core_dim_ixs`, equivalent to `cumsum(core_num_dims)`

char *core_signature

Core signature string

PyUFunc_TypeResolutionFunc *type_resolver

A function which resolves the types and fills an array with the dtypes for the inputs and outputs

type **PyUFunc_TypeResolutionFunc**

The function pointer type for `type_resolver`

numpy_uint32 op_flags

Override the default operand flags for each ufunc operand.

numpy_uint32 iter_flags

Override the default nditer flags for the ufunc.

Added in API version 0x0000000D

numpy_intp *core_dim_sizes

For each distinct core dimension, the possible *frozen* size if `UFUNC_CORE_DIM_SIZE_INFERRED` is 0

numpy_uint32 *core_dim_flags

For each distinct core dimension, a set of flags (`UFUNC_CORE_DIM_CAN_IGNORE` and `UFUNC_CORE_DIM_SIZE_INFERRED`)

PyObject *identity_value

Identity for reduction, when `PyUFuncObject.identity` is equal to `PyUFunc_IdentityValue`.

UFUNC_CORE_DIM_CAN_IGNORE

if the dim name ends in ?

UFUNC_CORE_DIM_SIZE_INFERRED

if the dim size will be determined from the operands and not from a *frozen* signature

PyArrayIter_Type and PyArrayIterObject

PyTypeObject PyArrayIter_Type

This is an iterator object that makes it easy to loop over an N-dimensional array. It is the object returned from the `flat` attribute of an ndarray. It is also used extensively throughout the implementation internals to loop over an N-dimensional array. The `tp_as_mapping` interface is implemented so that the iterator object can be indexed (using 1-d indexing), and a few methods are implemented through the `tp_methods` table. This object implements the `next` method and can be used anywhere an iterator can be used in Python.

type PyArrayIterObject

The C-structure corresponding to an object of *PyArrayIter_Type* is the *PyArrayIterObject*. The *PyArrayIterObject* is used to keep track of a pointer into an N-dimensional array. It contains associated information used to quickly march through the array. The pointer can be adjusted in three basic ways: 1) advance to the “next” position in the array in a C-style contiguous fashion, 2) advance to an arbitrary N-dimensional coordinate in the array, and 3) advance to an arbitrary one-dimensional index into the array. The members of the *PyArrayIterObject* structure are used in these calculations. Iterator objects keep their own dimension and strides information about an array. This can be adjusted as needed for “broadcasting,” or to loop over only specific dimensions.

```
typedef struct {
    PyObject_HEAD
    int    nd_m1;
    npy_intp index;
    npy_intp size;
    npy_intp coordinates[NPY_MAXDIMS_LEGACY_ITERS];
    npy_intp dims_m1[NPY_MAXDIMS_LEGACY_ITERS];
    npy_intp strides[NPY_MAXDIMS_LEGACY_ITERS];
    npy_intp backstrides[NPY_MAXDIMS_LEGACY_ITERS];
    npy_intp factors[NPY_MAXDIMS_LEGACY_ITERS];
    PyArrayObject *ao;
    char *dataptr;
    npy_bool contiguous;
} PyArrayIterObject;
```

int **nd_m1**

$N - 1$ where N is the number of dimensions in the underlying array.

npy_intp **index**

The current 1-d index into the array.

npy_intp **size**

The total size of the underlying array.

npy_intp ***coordinates**

An N -dimensional index into the array.

npy_intp ***dims_m1**

The size of the array minus 1 in each dimension.

npy_intp ***strides**

The strides of the array. How many bytes needed to jump to the next element in each dimension.

npy_intp ***backstrides**

How many bytes needed to jump from the end of a dimension back to its beginning. Note that `backstrides[k] == strides[k] * dims_m1[k]`, but it is stored here as an optimization.

numpy_intp ***factors**

This array is used in computing an N-d index from a 1-d index. It contains needed products of the dimensions.

PyArrayObject ***ao**

A pointer to the underlying ndarray this iterator was created to represent.

char ***dataptr**

This member points to an element in the ndarray indicated by the index.

numpy_bool **contiguous**

This flag is true if the underlying array is *NPY_ARRAY_C_CONTIGUOUS*. It is used to simplify calculations when possible.

How to use an array iterator on a C-level is explained more fully in later sections. Typically, you do not need to concern yourself with the internal structure of the iterator object, and merely interact with it through the use of the macros *PyArray_ITER_NEXT* (it), *PyArray_ITER_GOTO* (it, dest), or *PyArray_ITER_GOTO1D* (it, index). All of these macros require the argument *it* to be a *PyArrayIterObject**.

PyArrayMultiter_Type and PyArrayMultiterObject

PyTypeObject **PyArrayMultiIter_Type**

This type provides an iterator that encapsulates the concept of broadcasting. It allows N arrays to be broadcast together so that the loop progresses in C-style contiguous fashion over the broadcasted array. The corresponding C-structure is the *PyArrayMultiIterObject* whose memory layout must begin any object, *obj*, passed in to the *PyArray_Broadcast* (obj) function. Broadcasting is performed by adjusting array iterators so that each iterator represents the broadcasted shape and size, but has its strides adjusted so that the correct element from the array is used at each iteration.

type **PyArrayMultiIterObject**

```
typedef struct {
    PyObject_HEAD
    int numiter;
    numpy_intp size;
    numpy_intp index;
    int nd;
    numpy_intp dimensions[NPY_MAXDIMS_LEGACY_ITERS];
    PyArrayIterObject *iters[];
} PyArrayMultiIterObject;
```

int **numiter**

The number of arrays that need to be broadcast to the same shape.

numpy_intp **size**

The total broadcasted size.

numpy_intp **index**

The current (1-d) index into the broadcasted result.

int **nd**

The number of dimensions in the broadcasted result.

numpy_intp ***dimensions**

The shape of the broadcasted result (only nd slots are used).

PyArrayIterObject ****iters**

An array of iterator objects that holds the iterators for the arrays to be broadcast together. On return, the iterators are adjusted for broadcasting.

PyArrayNeighborhooIter_Type and PyArrayNeighborhooIterObject

PyTypeObject PyArrayNeighborhooIter_Type

This is an iterator object that makes it easy to loop over an N-dimensional neighborhood.

type PyArrayNeighborhooIterObject

The C-structure corresponding to an object of *PyArrayNeighborhooIter_Type* is the *PyArrayNeighborhooIterObject*.

```
typedef struct {
    PyObject_HEAD
    int nd_m1;
    npy_intp index, size;
    npy_intp coordinates[NPY_MAXDIMS_LEGACY_ITERS];
    npy_intp dims_m1[NPY_MAXDIMS_LEGACY_ITERS];
    npy_intp strides[NPY_MAXDIMS_LEGACY_ITERS];
    npy_intp backstrides[NPY_MAXDIMS_LEGACY_ITERS];
    npy_intp factors[NPY_MAXDIMS_LEGACY_ITERS];
    PyArrayObject *ao;
    char *dataptr;
    npy_bool contiguous;
    npy_intp bounds[NPY_MAXDIMS_LEGACY_ITERS][2];
    npy_intp limits[NPY_MAXDIMS_LEGACY_ITERS][2];
    npy_intp limits_sizes[NPY_MAXDIMS_LEGACY_ITERS];
    npy_iter_get_dataptr_t translate;
    npy_intp nd;
    npy_intp dimensions[NPY_MAXDIMS_LEGACY_ITERS];
    PyArrayIterObject* _internal_iter;
    char* constant;
    int mode;
} PyArrayNeighborhooIterObject;
```

ScalarArrayTypes

There is a Python type for each of the different built-in data types that can be present in the array. Most of these are simple wrappers around the corresponding data type in C. The C-names for these types are *Py{TYPE}ArrType_Type* where {TYPE} can be

Bool, Byte, Short, Int, Long, LongLong, UByte, UShort, UInt, ULong, ULongLong, Half, Float, Double, LongDouble, CFloat, CDouble, CLongDouble, String, Unicode, Void, Datetime, Timedelta, and Object.

These type names are part of the C-API and can therefore be created in extension C-code. There is also a *PyIntpArrType_Type* and a *PyUIntpArrType_Type* that are simple substitutes for one of the integer types that can hold a pointer on the platform. The structure of these scalar objects is not exposed to C-code. The function *PyArray_ScalarAsCtype* (..) can be used to extract the C-type value from the array scalar and the function *PyArray_Scalar* (...) can be used to construct an array scalar from a C-value.

Other C-structures

A few new C-structures were found to be useful in the development of NumPy. These C-structures are used in at least one C-API call and are therefore documented here. The main reason these structures were defined is to make it easy to use the Python ParseTuple C-API to convert from Python objects to a useful C-Object.

PyArray_Dims

type **PyArray_Dims**

This structure is very useful when shape and/or strides information is supposed to be interpreted. The structure is:

```
typedef struct {
    npy_intp *ptr;
    int len;
} PyArray_Dims;
```

The members of this structure are

npy_intp ***ptr**

A pointer to a list of (*npy_intp*) integers which usually represent array shape or array strides.

int **len**

The length of the list of integers. It is assumed safe to access *ptr* [0] to *ptr* [len-1].

PyArray_Chunk

type **PyArray_Chunk**

This is equivalent to the buffer object structure in Python up to the ptr member. On 32-bit platforms (*i.e.* if `NPY_SIZEOF_INT == NPY_SIZEOF_INTP`), the len member also matches an equivalent member of the buffer object. It is useful to represent a generic single-segment chunk of memory.

```
typedef struct {
    PyObject_HEAD
    PyObject *base;
    void *ptr;
    npy_intp len;
    int flags;
} PyArray_Chunk;
```

The members are

PyObject ***base**

The Python object this chunk of memory comes from. Needed so that memory can be accounted for properly.

void ***ptr**

A pointer to the start of the single-segment chunk of memory.

npy_intp **len**

The length of the segment in bytes.

int **flags**

Any data flags (*e.g.* `NPY_ARRAY_WRITEABLE`) that should be used to interpret the memory.

PyArrayInterface

See also:

The array interface protocol

type **PyArrayInterface**

The *PyArrayInterface* structure is defined so that NumPy and other extension modules can use the rapid array interface protocol. The `__array_struct__` method of an object that supports the rapid array interface protocol should return a *PyCapsule* that contains a pointer to a *PyArrayInterface* structure with the relevant details of the array. After the new array is created, the attribute should be DECREMENTED which will free the *PyArrayInterface* structure. Remember to INCREMENT the object (whose `__array_struct__` attribute was retrieved) and point the base member of the new *PyArrayObject* to this same object. In this way the memory for the array will be managed correctly.

```
typedef struct {
    int two;
    int nd;
    char typekind;
    int itemsize;
    int flags;
    npy_intp *shape;
    npy_intp *strides;
    void *data;
    PyObject *descr;
} PyArrayInterface;
```

int **two**

the integer 2 as a sanity check.

int **nd**

the number of dimensions in the array.

char **typekind**

A character indicating what kind of array is present according to the typestring convention with 't' -> bitfield, 'b' -> Boolean, 'i' -> signed integer, 'u' -> unsigned integer, 'f' -> floating point, 'c' -> complex floating point, 'O' -> object, 'S' -> (byte-)string, 'U' -> unicode, 'V' -> void.

int **itemsize**

The number of bytes each item in the array requires.

int **flags**

Any of the bits `NPY_ARRAY_C_CONTIGUOUS` (1), `NPY_ARRAY_F_CONTIGUOUS` (2), `NPY_ARRAY_ALIGNED` (0x100), `NPY_ARRAY_NOTSWAPPED` (0x200), or `NPY_ARRAY_WRITEABLE` (0x400) to indicate something about the data. The `NPY_ARRAY_ALIGNED`, `NPY_ARRAY_C_CONTIGUOUS`, and `NPY_ARRAY_F_CONTIGUOUS` flags can actually be determined from the other parameters. The flag `NPY_ARR_HAS_DESCR` (0x800) can also be set to indicate to objects consuming the version 3 array interface that the `descr` member of the structure is present (it will be ignored by objects consuming version 2 of the array interface).

npy_intp ***shape**

An array containing the size of the array in each dimension.

npy_intp ***strides**

An array containing the number of bytes to jump to get to the next element in each dimension.

void ***data**

A pointer to the first element of the array.

PyObject *descr

A Python object describing the data-type in more detail (same as the *descr* key in `__array_interface__`). This can be NULL if *typekind* and *itemsize* provide enough information. This field is also ignored unless `NPY_ARR_HAS_DESCR` flag is on in *flags*.

Internally used structures

Internally, the code uses some additional Python objects primarily for memory management. These types are not accessible directly from Python, and are not exposed to the C-API. They are included here only for completeness and assistance in understanding the code.

type PyUFunc_Loop1d

A simple linked-list of C-structures containing the information needed to define a 1-d loop for a ufunc for every defined signature of a user-defined data-type.

PyTypeObject PyArrayMapIter_Type

Advanced indexing is handled with this Python type. It is simply a loose wrapper around the C-structure containing the variables needed for advanced array indexing.

type PyArrayMapIterObject

The C-structure associated with `PyArrayMapIter_Type`. This structure is useful if you are trying to understand the advanced-index mapping code. It is defined in the `multiarray/mapping.h` header. This type is not exposed to Python and could be replaced with a C-structure. As a Python type it takes advantage of reference-counted memory management.

NumPy C-API and C complex

When you use the NumPy C-API, you will have access to complex real declarations `np_cdouble` and `np_cfloat`, which are declared in terms of the C standard types from `complex.h`. Unfortunately, `complex.h` contains `#define I ...` (where the actual definition depends on the compiler), which means that any downstream user that does `#include <numpy/arrayobject.h>` could get `I` defined, and using something like declaring `double I`; in their code will result in an obscure compiler error like

This error can be avoided by adding:

```
#undef I
```

to your code.

Changed in version 2.0: The inclusion of `complex.h` was new in NumPy 2, so that code defining a different `I` may not have required the `#undef I` on older versions. NumPy 2.0.1 briefly included the `#undef I`

2.1.2 System configuration

When NumPy is built, information about system configuration is recorded, and is made available for extension modules using NumPy's C API. These are mostly defined in `numpyconfig.h` (included in `ndarrayobject.h`). The public symbols are prefixed by `NPY_*`. NumPy also offers some functions for querying information about the platform in use.

For private use, NumPy also constructs a `config.h` in the NumPy include directory, which is not exported by NumPy (that is a python extension which use the numpy C API will not see those symbols), to avoid namespace pollution.

Data type sizes

The `NPY_SIZEOF_{CTYPE}` constants are defined so that `sizeof` information is available to the pre-processor.

NPY_SIZEOF_SHORT

`sizeof(short)`

NPY_SIZEOF_INT

`sizeof(int)`

NPY_SIZEOF_LONG

`sizeof(long)`

NPY_SIZEOF_LONGLONG

`sizeof(longlong)` where `longlong` is defined appropriately on the platform.

NPY_SIZEOF_PY_LONG_LONG

NPY_SIZEOF_FLOAT

`sizeof(float)`

NPY_SIZEOF_DOUBLE

`sizeof(double)`

NPY_SIZEOF_LONG_DOUBLE

NPY_SIZEOF_LONGDOUBLE

`sizeof(longdouble)`

NPY_SIZEOF_PY_INTPTR_T

Size of a pointer `void *` and `intptr_t/Py_intptr_t`.

NPY_SIZEOF_INTP

Size of a `size_t` on this platform (`sizeof(size_t)`)

Platform information

NPY_CPU_X86

NPY_CPU_AMD64

NPY_CPU_IA64

NPY_CPU_PPC

NPY_CPU_PPC64

NPY_CPU_SPARC

NPY_CPU_SPARC64

NPY_CPU_S390

NPY_CPU_PARISC

CPU architecture of the platform; only one of the above is defined.

Defined in `numpy/np_cpu.h`

NPY_LITTLE_ENDIAN**NPY_BIG_ENDIAN****NPY_BYTE_ORDER**

Portable alternatives to the `endian.h` macros of GNU Libc. If big endian, `NPY_BYTE_ORDER == NPY_BIG_ENDIAN`, and similarly for little endian architectures.

Defined in `numpy/np_endian.h`.

int PyArray_GetEndianness()

Returns the endianness of the current platform. One of `NPY_CPU_BIG`, `NPY_CPU_LITTLE`, or `NPY_CPU_UNKNOWN_ENDIAN`.

NPY_CPU_BIG**NPY_CPU_LITTLE****NPY_CPU_UNKNOWN_ENDIAN**

Compiler directives

NPY_LIKELY**NPY_UNLIKELY****NPY_UNUSED**

2.1.3 Data type API

The standard array can have 25 different data types (and has some support for adding your own types). These data types all have an enumerated type, an enumerated type-character, and a corresponding array scalar Python type object (placed in a hierarchy). There are also standard C typedefs to make it easier to manipulate elements of the given data type. For the numeric types, there are also bit-width equivalent C typedefs and named typenumbers that make it easier to select the precision desired.

Warning: The names for the types in c code follows c naming conventions more closely. The Python names for these types follow Python conventions. Thus, `NPY_FLOAT` picks up a 32-bit float in C, but `numpy.float64` in Python corresponds to a 64-bit double. The bit-width names can be used in both Python and C for clarity.

Enumerated types

enum NPY_TYPES

There is a list of enumerated types defined providing the basic 25 data types plus some useful generic names. Whenever the code requires a type number, one of these enumerated types is requested. The types are all called `NPY_{NAME}`:

enumerator NPY_BOOL

The enumeration value for the boolean type, stored as one byte. It may only be set to the values 0 and 1.

enumerator NPY_BYTE

enumerator **NPY_INT8**

The enumeration value for an 8-bit/1-byte signed integer.

enumerator **NPY_SHORT**

enumerator **NPY_INT16**

The enumeration value for a 16-bit/2-byte signed integer.

enumerator **NPY_INT**

enumerator **NPY_INT32**

The enumeration value for a 32-bit/4-byte signed integer.

enumerator **NPY_LONG**

Equivalent to either NPY_INT or NPY_LONGLONG, depending on the platform.

enumerator **NPY_LONGLONG**

enumerator **NPY_INT64**

The enumeration value for a 64-bit/8-byte signed integer.

enumerator **NPY_UBYTE**

enumerator **NPY_UINT8**

The enumeration value for an 8-bit/1-byte unsigned integer.

enumerator **NPY_USHORT**

enumerator **NPY_UINT16**

The enumeration value for a 16-bit/2-byte unsigned integer.

enumerator **NPY_UINT**

enumerator **NPY_UINT32**

The enumeration value for a 32-bit/4-byte unsigned integer.

enumerator **NPY_ULONG**

Equivalent to either NPY_UINT or NPY_ULONGLONG, depending on the platform.

enumerator **NPY_ULONGLONG**

enumerator **NPY_UINT64**

The enumeration value for a 64-bit/8-byte unsigned integer.

enumerator **NPY_HALF**

enumerator **NPY_FLOAT16**

The enumeration value for a 16-bit/2-byte IEEE 754-2008 compatible floating point type.

enumerator **NPY_FLOAT**

enumerator **NPY_FLOAT32**

The enumeration value for a 32-bit/4-byte IEEE 754 compatible floating point type.

enumerator **NPY_DOUBLE**

enumerator **NPY_FLOAT64**

The enumeration value for a 64-bit/8-byte IEEE 754 compatible floating point type.

enumerator **NPY_LONGDOUBLE**

The enumeration value for a platform-specific floating point type which is at least as large as NPY_DOUBLE, but larger on many platforms.

enumerator **NPY_CFLOAT**

enumerator **NPY_COMPLEX64**

The enumeration value for a 64-bit/8-byte complex type made up of two NPY_FLOAT values.

enumerator **NPY_CDOUBLE**

enumerator **NPY_COMPLEX128**

The enumeration value for a 128-bit/16-byte complex type made up of two NPY_DOUBLE values.

enumerator **NPY_CLONGDOUBLE**

The enumeration value for a platform-specific complex floating point type which is made up of two NPY_LONGDOUBLE values.

enumerator **NPY_DATETIME**

The enumeration value for a data type which holds dates or datetimes with a precision based on selectable date or time units.

enumerator **NPY_TIMEDELTA**

The enumeration value for a data type which holds lengths of times in integers of selectable date or time units.

enumerator **NPY_STRING**

The enumeration value for null-padded byte strings of a selectable size. The strings have a fixed maximum size within a given array.

enumerator **NPY_UNICODE**

The enumeration value for UCS4 strings of a selectable size. The strings have a fixed maximum size within a given array.

enumerator **NPY_VSTRING**

The enumeration value for UTF-8 variable-width strings. Note that this dtype holds an array of references, with string data stored outside of the array buffer. Use the C API for working with numpy variable-width static strings to access the string data in each array entry.

Note: This DType is new-style and is not included in NPY_NTYPES_LEGACY.

enumerator **NPY_OBJECT**

The enumeration value for references to arbitrary Python objects.

enumerator **NPY_VOID**

Primarily used to hold struct dtypes, but can contain arbitrary binary data.

Some useful aliases of the above types are

enumerator **NPY_INTP**

The enumeration value for a signed integer of type `Py_ssize_t` (same as `ssize_t` if defined). This is the type used by all arrays of indices.

Changed in version 2.0: Previously, this was the same as `intptr_t` (same size as a pointer). In practice, this is identical except on very niche platforms. You can use the `'p'` character code for the pointer meaning.

enumerator `NPY_UINTP`

The enumeration value for an unsigned integer type that is identical to a `size_t`.

Changed in version 2.0: Previously, this was the same as `uintptr_t` (same size as a pointer). In practice, this is identical except on very niche platforms. You can use the 'P' character code for the pointer meaning.

enumerator `NPY_MASK`

The enumeration value of the type used for masks, such as with the `NPY_ITER_ARRAYMASK` iterator flag. This is equivalent to `NPY_UINT8`.

enumerator `NPY_DEFAULT_TYPE`

The default type to use when no dtype is explicitly specified, for example when calling `np.zeros(shape)`. This is equivalent to `NPY_DOUBLE`.

Other useful related constants are

`NPY_NTYPES_LEGACY`

The number of built-in NumPy types written using the legacy DType system. New NumPy dtypes will be written using the new DType API and may not function in the same manner as legacy DTypes. Use this macro if you want to handle legacy DTypes using different code paths or if you do not want to update code that uses `NPY_NTYPES_LEGACY` and does not work correctly with new DTypes.

Note: Newly added DTypes such as `NPY_VSTRING` will not be counted in `NPY_NTYPES_LEGACY`.

`NPY_NOTYPE`

A signal value guaranteed not to be a valid type enumeration number.

`NPY_USERDEF`

The start of type numbers used for legacy Custom Data types. New-style user DTypes currently are currently *not* assigned a type-number.

Note: The total number of user dtypes is limited to below `NPY_VSTRING`. Higher numbers are reserved to future new-style DType use.

The various character codes indicating certain types are also part of an enumerated list. References to type characters (should they be needed at all) should always use these enumerations. The form of them is `NPY_{NAME}LTR` where `{NAME}` can be

BOOL, BYTE, UBYTE, SHORT, USHORT, INT, UINT, LONG, ULONG, LONGLONG, ULONGLONG, HALF, FLOAT, DOUBLE, LONGDOUBLE, CFLOAT, CDOUBLE, CLONGDOUBLE, DATETIME, TIMEDelta, OBJECT, STRING, UNICODE, VSTRING, VOID

INTP, UINTP

GENBOOL, SIGNED, UNSIGNED, FLOATING, COMPLEX

The latter group of `{NAME}`s corresponds to letters used in the array interface typestring specification.

Defines

Max and min values for integers

NPY_MAX_INT{bits}, NPY_MAX_UINT{bits}, NPY_MIN_INT{bits}

These are defined for {bits} = 8, 16, 32, 64, 128, and 256 and provide the maximum (minimum) value of the corresponding (unsigned) integer type. Note: the actual integer type may not be available on all platforms (i.e. 128-bit and 256-bit integers are rare).

NPY_MIN_{type}

This is defined for {type} = **BYTE, SHORT, INT, LONG, LONGLONG, INTP**

NPY_MAX_{type}

This is defined for all defined for {type} = **BYTE, UBYTE, SHORT, USHORT, INT, UINT, LONG, ULONG, LONGLONG, ULLONGLONG, INTP, UINTP**

Number of bits in data types

All **NPY_SIZEOF_{CTYPE}** constants have corresponding **NPY_BITSOFF_{CTYPE}** constants defined. The **NPY_BITSOFF_{CTYPE}** constants provide the number of bits in the data type. Specifically, the available {CTYPE}s are

BOOL, CHAR, SHORT, INT, LONG, LONGLONG, FLOAT, DOUBLE, LONGDOUBLE

Bit-width references to enumerated typenums

All of the numeric data types (integer, floating point, and complex) have constants that are defined to be a specific enumerated type number. Exactly which enumerated type a bit-width type refers to is platform dependent. In particular, the constants available are **PyArray_{NAME}{BITS}** where {NAME} is **INT, UINT, FLOAT, COMPLEX** and {BITS} can be 8, 16, 32, 64, 80, 96, 128, 160, 192, 256, and 512. Obviously not all bit-widths are available on all platforms for all the kinds of numeric types. Commonly 8-, 16-, 32-, 64-bit integers; 32-, 64-bit floats; and 64-, 128-bit complex types are available.

Further integer aliases

The constants **NPY_INTP** and **NPY_UINTP** refer to an `Py_ssize_t` and `size_t`. Although in practice normally true, these types are strictly speaking not pointer sized and the character codes 'p' and 'P' can be used for pointer sized integers. (Before NumPy 2, `intp` was pointer size, but this almost never matched the actual use, which is the reason for the name.)

Since NumPy 2, **NPY_DEFAULT_INT** is additionally defined. The value of the macro is runtime dependent: Since NumPy 2, it maps to **NPY_INTP** while on earlier versions it maps to **NPY_LONG**.

C-type names

There are standard variable types for each of the numeric data types and the bool data type. Some of these are already available in the C-specification. You can create variables in extension code with these types.

Boolean

type **numpy_bool**

unsigned char; The constants *NPY_FALSE* and *NPY_TRUE* are also defined.

(Un)Signed Integer

Unsigned versions of the integers can be defined by prepending a ‘u’ to the front of the integer name.

type **numpy_byte**

char

type **numpy_ubyte**

unsigned char

type **numpy_short**

short

type **numpy_ushort**

unsigned short

type **numpy_int**

int

type **numpy_uint**

unsigned int

type **numpy_int16**

16-bit integer

type **numpy_uint16**

16-bit unsigned integer

type **numpy_int32**

32-bit integer

type **numpy_uint32**

32-bit unsigned integer

type **numpy_int64**

64-bit integer

type **numpy_uint64**

64-bit unsigned integer

type **numpy_long**

long int

type **numpy_ulong**

unsigned long int

type **numpy_longlong**

long long int

type **numpy_ulonglong**

unsigned long long int

type **numpy_intp**

`Py_ssize_t` (a signed integer with the same size as the `C size_t`). This is the correct integer for lengths or indexing. In practice this is normally the size of a pointer, but this is not guaranteed.

Note: Before NumPy 2.0, this was the same as `Py_intptr_t`. While a better match, this did not match actual usage in practice. On the Python side, we still support `np.dtype('p')` to fetch a dtype compatible with storing pointers, while `n` is the correct character for the `ssize_t`.

type **numpy_uintp**

The `C size_t/Py_size_t`.

(Complex) Floating point

type **numpy_half**

16-bit float

type **numpy_float**

32-bit float

type **numpy_cfloat**

32-bit complex float

type **numpy_double**

64-bit double

type **numpy_cdouble**

64-bit complex double

type **numpy_longdouble**

long double

type **numpy_clongdouble**

long complex double

complex types are structures with **.real** and **.imag** members (in that order).

Bit-width names

There are also typedefs for signed integers, unsigned integers, floating point, and complex floating point types of specific bit-widths. The available type names are

`numpy_int{bits}`, `numpy_uint{bits}`, `numpy_float{bits}`, and `numpy_complex{bits}`

where `{bits}` is the number of bits in the type and can be **8**, **16**, **32**, **64**, 128, and 256 for integer types; 16, **32**, **64**, 80, 96, 128, and 256 for floating-point types; and 32, **64**, **128**, 160, 192, and 512 for complex-valued types. Which bit-widths are available is platform dependent. The bolded bit-widths are usually available on all platforms.

Time and timedelta

type **numpy_datetime**

date or datetime (alias of `numpy_int64`)

type **numpy_timedelta**

length of time (alias of `numpy_int64`)

Printf formatting

For help in printing, the following strings are defined as the correct format specifier in printf and related commands.

NPY_LONGLONG_FMT

NPY_ULONGLONG_FMT

NPY_INTP_FMT

NPY_UINTP_FMT

NPY_LONGDOUBLE_FMT

2.1.4 Array API

The test of a first-rate intelligence is the ability to hold two opposed ideas in the mind at the same time, and still retain the ability to function.

— *F. Scott Fitzgerald*

For a successful technology, reality must take precedence over public relations, for Nature cannot be fooled.

— *Richard P. Feynman*

Array structure and data access

These macros access the *PyArrayObject* structure members and are defined in `ndarraytypes.h`. The input argument, *arr*, can be any *PyObject** that is directly interpretable as a *PyArrayObject** (any instance of the *PyArray_Type* and its sub-types).

`int PyArray_NDIM (PyArrayObject *arr)`

The number of dimensions in the array.

`int PyArray_FLAGS (PyArrayObject *arr)`

Returns an integer representing the *array-flags*.

`int PyArray_TYPE (PyArrayObject *arr)`

Return the (builtin) typenumber for the elements of this array.

`int PyArray_Pack (const PyArray_Descr *descr, void *item, const PyObject *value)`

New in version 2.0.

Sets the memory location *item* of dtype *descr* to *value*.

The function is equivalent to setting a single array element with a Python assignment. Returns 0 on success and -1 with an error set on failure.

Note: If the *descr* has the *NPY_NEEDS_INIT* flag set, the data must be valid or the memory zeroed.

`int PyArray_SETITEM (PyArrayObject *arr, void *itemptr, PyObject *obj)`

Convert *obj* and place it in the ndarray, *arr*, at the place pointed to by *itemptr*. Return -1 if an error occurs or 0 on success.

Note: In general, prefer the use of *PyArray_Pack* when handling arbitrary Python objects. *Setitem* is for example not able to handle arbitrary casts between different dtypes.

`void PyArray_ENABLEFLAGS (PyArrayObject *arr, int flags)`

Enables the specified array flags. This function does no validation, and assumes that you know what you're doing.

`void PyArray_CLEARFLAGS (PyArrayObject *arr, int flags)`

Clears the specified array flags. This function does no validation, and assumes that you know what you're doing.

`void *PyArray_DATA (PyArrayObject *arr)`

`char *PyArray_BYTES (PyArrayObject *arr)`

These two macros are similar and obtain the pointer to the data-buffer for the array. The first macro can (and should be) assigned to a particular pointer where the second is for generic processing. If you have not guaranteed a contiguous and/or aligned array then be sure you understand how to access the data in the array to avoid memory and/or alignment problems.

`numpy_intp *PyArray_DIMS (PyArrayObject *arr)`

Returns a pointer to the dimensions/shape of the array. The number of elements matches the number of dimensions of the array. Can return NULL for 0-dimensional arrays.

`numpy_intp *PyArray_SHAPE (PyArrayObject *arr)`

A synonym for *PyArray_DIMS*, named to be consistent with the *shape* usage within Python.

`numpy_intp *PyArray_STRIDES (PyArrayObject *arr)`

Returns a pointer to the strides of the array. The number of elements matches the number of dimensions of the array.

`numpy_intp PyArray_DIM (PyArrayObject *arr, int n)`

Return the shape in the n^{th} dimension.

`numpy_intp PyArray_STRIDE (PyArrayObject *arr, int n)`

Return the stride in the n^{th} dimension.

`numpy_intp PyArray_ITEMSIZE (PyArrayObject *arr)`

Return the itemsize for the elements of this array.

Note that, in the old API that was deprecated in version 1.7, this function had the return type `int`.

`numpy_intp PyArray_SIZE (PyArrayObject *arr)`

Returns the total size (in number of elements) of the array.

`numpy_intp PyArray_Size (PyObject *obj)`

Returns 0 if *obj* is not a sub-class of ndarray. Otherwise, returns the total number of elements in the array. Safer version of *PyArray_SIZE* (*obj*).

`numpy_intp PyArray_NBYTES (PyArrayObject *arr)`

Returns the total number of bytes consumed by the array.

`PyObject *PyArray_BASE (PyArrayObject *arr)`

This returns the base object of the array. In most cases, this means the object which owns the memory the array is pointing at.

If you are constructing an array using the C API, and specifying your own memory, you should use the function `PyArray_SetBaseObject` to set the base to an object which owns the memory.

If the `NPY_ARRAY_WRITEBACKIFCOPY` flag is set, it has a different meaning, namely base is the array into which the current array will be copied upon copy resolution. This overloading of the base property for two functions is likely to change in a future version of NumPy.

`PyArray_Descr *PyArray_DESCR (PyArrayObject *arr)`

Returns a borrowed reference to the dtype property of the array.

`PyArray_Descr *PyArray_DTYPE (PyArrayObject *arr)`

A synonym for `PyArray_DESCR`, named to be consistent with the ‘dtype’ usage within Python.

`PyObject *PyArray_GETITEM (PyArrayObject *arr, void *itemptr)`

Get a Python object of a builtin type from the ndarray, *arr*, at the location pointed to by *itemptr*. Return `NULL` on failure.

`numpy.ndarray.item` is identical to `PyArray_GETITEM`.

`int PyArray_FinalizeFunc (PyArrayObject *arr, PyObject *obj)`

The function pointed to by the `PyCapsule __array_finalize__`. The first argument is the newly created sub-type. The second argument (if not `NULL`) is the “parent” array (if the array was created using slicing or some other operation where a clearly-distinguishable parent is present). This routine can do anything it wants to. It should return a -1 on error and 0 otherwise.

Data access

These functions and macros provide easy access to elements of the ndarray from C. These work for all arrays. You may need to take care when accessing the data in the array, however, if it is not in machine byte-order, misaligned, or not writeable. In other words, be sure to respect the state of the flags unless you know what you are doing, or have previously guaranteed an array that is writeable, aligned, and in machine byte-order using `PyArray_FromAny`. If you wish to handle all types of arrays, the `copyswap` function for each type is useful for handling misbehaved arrays. Some platforms (e.g. Solaris) do not like misaligned data and will crash if you de-reference a misaligned pointer. Other platforms (e.g. x86 Linux) will just work more slowly with misaligned data.

`void *PyArray_GetPtr (PyArrayObject *aobj, npy_intp *ind)`

Return a pointer to the data of the ndarray, *aobj*, at the N-dimensional index given by the c-array, *ind*, (which must be at least *aobj* ->nd in size). You may want to typecast the returned pointer to the data type of the ndarray.

`void *PyArray_GETPTR1 (PyArrayObject *obj, npy_intp i)`

`void *PyArray_GETPTR2 (PyArrayObject *obj, npy_intp i, npy_intp j)`

`void *PyArray_GETPTR3 (PyArrayObject *obj, npy_intp i, npy_intp j, npy_intp k)`

`void *PyArray_GETPTR4 (PyArrayObject *obj, npy_intp i, npy_intp j, npy_intp k, npy_intp l)`

Quick, inline access to the element at the given coordinates in the ndarray, *obj*, which must have respectively 1, 2, 3, or 4 dimensions (this is not checked). The corresponding *i*, *j*, *k*, and *l* coordinates can be any integer but will be interpreted as `npy_intp`. You may want to typecast the returned pointer to the data type of the ndarray.

Creating arrays

From scratch

PyObject *PyArray_NewFromDescr (PyObject *subtype, PyArray_Descr *descr, int nd, npy_intp const *dims, npy_intp const *strides, void *data, int flags, PyObject *obj)

This function steals a reference to *descr*. The easiest way to get one is using *PyArray_DescrFromType*.

This is the main array creation function. Most new arrays are created with this flexible function.

The returned object is an object of Python-type *subtype*, which must be a subtype of *PyArray_Type*. The array has *nd* dimensions, described by *dims*. The data-type descriptor of the new array is *descr*.

If *subtype* is of an array subclass instead of the base *&PyArray_Type*, then *obj* is the object to pass to the *__array_finalize__* method of the subclass.

If *data* is NULL, then new uninitialized memory will be allocated and *flags* can be non-zero to indicate a Fortran-style contiguous array. Use *PyArray_FILLWBYTE* to initialize the memory.

If *data* is not NULL, then it is assumed to point to the memory to be used for the array and the *flags* argument is used as the new flags for the array (except the state of *NPY_ARRAY_OWNDATA*, *NPY_ARRAY_WRITEBACKIFCOPY* flag of the new array will be reset).

In addition, if *data* is non-NULL, then *strides* can also be provided. If *strides* is NULL, then the array strides are computed as C-style contiguous (default) or Fortran-style contiguous (*flags* is nonzero for *data* = NULL or *flags* & *NPY_ARRAY_F_CONTIGUOUS* is nonzero non-NULL *data*). Any provided *dims* and *strides* are copied into newly allocated dimension and strides arrays for the new array object.

PyArray_CheckStrides can help verify non- NULL stride information.

If *data* is provided, it must stay alive for the life of the array. One way to manage this is through *PyArray_SetBaseObject*

PyObject *PyArray_NewLikeArray (PyArrayObject *prototype, NPY_ORDER order, PyArray_Descr *descr, int subok)

This function steals a reference to *descr* if it is not NULL. This array creation routine allows for the convenient creation of a new array matching an existing array's shapes and memory layout, possibly changing the layout and/or data type.

When *order* is *NPY_ANYORDER*, the result order is *NPY_FORTTRANORDER* if *prototype* is a fortran array, *NPY_CORDER* otherwise. When *order* is *NPY_KEEPOORDER*, the result order matches that of *prototype*, even when the axes of *prototype* aren't in C or Fortran order.

If *descr* is NULL, the data type of *prototype* is used.

If *subok* is 1, the newly created array will use the sub-type of *prototype* to create the new array, otherwise it will create a base-class array.

PyObject *PyArray_New (PyObject *subtype, int nd, npy_intp const *dims, int type_num, npy_intp const *strides, void *data, int itemsize, int flags, PyObject *obj)

This is similar to *PyArray_NewFromDescr* (...) except you specify the data-type descriptor with *type_num* and *itemsize*, where *type_num* corresponds to a builtin (or user-defined) type. If the type always has the same number of bytes, then *itemsize* is ignored. Otherwise, *itemsize* specifies the particular size of this array.

Warning: If data is passed to *PyArray_NewFromDescr* or *PyArray_New*, this memory must not be deallocated until the new array is deleted. If this data came from another Python object, this can be accomplished using *Py_INCREF* on that object and setting the base member of the new array to point to that object. If strides are passed in they must be consistent with the dimensions, the itemsize, and the data of the array.

PyObject *PyArray_SimpleNew (int nd, *numpy_intp* const *dims, int typenum)

Create a new uninitialized array of type, *typenum*, whose size in each of *nd* dimensions is given by the integer array, *dims*. The memory for the array is uninitialized (unless *typenum* is *NPY_OBJECT* in which case each element in the array is set to NULL). The *typenum* argument allows specification of any of the builtin data-types such as *NPY_FLOAT* or *NPY_LONG*. The memory for the array can be set to zero if desired using *PyArray_FILLWBYTE* (return_object, 0). This function cannot be used to create a flexible-type array (no item-size given).

PyObject *PyArray_SimpleNewFromData (int nd, *numpy_intp* const *dims, int typenum, void *data)

Create an array wrapper around *data* pointed to by the given pointer. The array flags will have a default that the data area is well-behaved and C-style contiguous. The shape of the array is given by the *dims* c-array of length *nd*. The data-type of the array is indicated by *typenum*. If data comes from another reference-counted Python object, the reference count on this object should be increased after the pointer is passed in, and the base member of the returned ndarray should point to the Python object that owns the data. This will ensure that the provided memory is not freed while the returned array is in existence.

PyObject *PyArray_SimpleNewFromDescr (int nd, *numpy_intp* const *dims, *PyArray_Descr* *descr)

This function steals a reference to *descr*.

Create a new array with the provided data-type descriptor, *descr*, of the shape determined by *nd* and *dims*.

void **PyArray_FILLWBYTE** (*PyObject* *obj, int val)

Fill the array pointed to by *obj* —which must be a (subclass of) ndarray—with the contents of *val* (evaluated as a byte). This macro calls *memset*, so *obj* must be contiguous.

PyObject *PyArray_Zeros (int nd, *numpy_intp* const *dims, *PyArray_Descr* *dtype, int fortran)

Construct a new *nd* -dimensional array with shape given by *dims* and data type given by *dtype*. If *fortran* is non-zero, then a Fortran-order array is created, otherwise a C-order array is created. Fill the memory with zeros (or the 0 object if *dtype* corresponds to *NPY_OBJECT*).

PyObject *PyArray_ZEROS (int nd, *numpy_intp* const *dims, int type_num, int fortran)

Macro form of *PyArray_Zeros* which takes a type-number instead of a data-type object.

PyObject *PyArray_Empty (int nd, *numpy_intp* const *dims, *PyArray_Descr* *dtype, int fortran)

Construct a new *nd* -dimensional array with shape given by *dims* and data type given by *dtype*. If *fortran* is non-zero, then a Fortran-order array is created, otherwise a C-order array is created. The array is uninitialized unless the data type corresponds to *NPY_OBJECT* in which case the array is filled with *Py_None*.

PyObject *PyArray_EMPTY (int nd, *numpy_intp* const *dims, int typenum, int fortran)

Macro form of *PyArray_Empty* which takes a type-number, *typenum*, instead of a data-type object.

PyObject *PyArray_Arange (double start, double stop, double step, int typenum)

Construct a new 1-dimensional array of data-type, *typenum*, that ranges from *start* to *stop* (exclusive) in increments of *step* . Equivalent to *arange* (*start*, *stop*, *step*, *dtype*).

PyObject *PyArray_ArangeObj (*PyObject* *start, *PyObject* *stop, *PyObject* *step, *PyArray_Descr* *descr)

Construct a new 1-dimensional array of data-type determined by *descr*, that ranges from *start* to *stop* (exclusive) in increments of *step*. Equivalent to *arange*(*start*, *stop*, *step*, *typenum*).

int **PyArray_SetBaseObject** (*PyArrayObject* *arr, *PyObject* *obj)

This function **steals a reference** to *obj* and sets it as the base property of *arr*.

If you construct an array by passing in your own memory buffer as a parameter, you need to set the array's *base* property to ensure the lifetime of the memory buffer is appropriate.

The return value is 0 on success, -1 on failure.

If the object provided is an array, this function traverses the chain of *base* pointers so that each array points to the owner of the memory directly. Once the base is set, it may not be changed to another value.

From other objects

`PyObject *PyArray_FromAny` (`PyObject *op`, `PyArray_Descr *dtype`, `int min_depth`, `int max_depth`, `int requirements`, `PyObject *context`)

This is the main function used to obtain an array from any nested sequence, or object that exposes the array interface, *op*. The parameters allow specification of the required *dtype*, the minimum (*min_depth*) and maximum (*max_depth*) number of dimensions acceptable, and other *requirements* for the array. This function **steals a reference** to the *dtype* argument, which needs to be a `PyArray_Descr` structure indicating the desired data-type (including required byteorder). The *dtype* argument may be `NULL`, indicating that any data-type (and byteorder) is acceptable. Unless `NPY_ARRAY_FORCECAST` is present in *flags*, this call will generate an error if the data type cannot be safely obtained from the object. If you want to use `NULL` for the *dtype* and ensure the array is not swapped then use `PyArray_CheckFromAny`. A value of 0 for either of the depth parameters causes the parameter to be ignored. Any of the following array flags can be added (e.g. using `|`) to get the *requirements* argument. If your code can handle general (e.g. strided, byte-swapped, or unaligned arrays) then *requirements* may be 0. Also, if *op* is not already an array (or does not expose the array interface), then a new array will be created (and filled from *op* using the sequence protocol). The new array will have `NPY_ARRAY_DEFAULT` as its flags member. The *context* argument is unused.

`NPY_ARRAY_C_CONTIGUOUS`

Make sure the returned array is C-style contiguous

`NPY_ARRAY_F_CONTIGUOUS`

Make sure the returned array is Fortran-style contiguous.

`NPY_ARRAY_ALIGNED`

Make sure the returned array is aligned on proper boundaries for its data type. An aligned array has the data pointer and every strides factor as a multiple of the alignment factor for the data-type- descriptor.

`NPY_ARRAY_WRITEABLE`

Make sure the returned array can be written to.

`NPY_ARRAY_ENSURECOPY`

Make sure a copy is made of *op*. If this flag is not present, data is not copied if it can be avoided.

`NPY_ARRAY_ENSUREARRAY`

Make sure the result is a base-class ndarray. By default, if *op* is an instance of a subclass of ndarray, an instance of that same subclass is returned. If this flag is set, an ndarray object will be returned instead.

`NPY_ARRAY_FORCECAST`

Force a cast to the output type even if it cannot be done safely. Without this flag, a data cast will occur only if it can be done safely, otherwise an error is raised.

`NPY_ARRAY_WRITEBACKIFCOPY`

If *op* is already an array, but does not satisfy the requirements, then a copy is made (which will satisfy the requirements). If this flag is present and a copy (of an object that is already an array) must be made, then the corresponding `NPY_ARRAY_WRITEBACKIFCOPY` flag is set in the returned copy and *op* is made to be read-only. You must be sure to call `PyArray_ResolveWritebackIfCopy` to copy the contents back into *op* and the *op* array will be made writeable again. If *op* is not writeable to begin with, or if it is not already an array, then an error is raised.

Combinations of array flags can also be added.

`PyObject *PyArray_CheckFromAny` (`PyObject *op`, `PyArray_Descr *dtype`, `int min_depth`, `int max_depth`, `int requirements`, `PyObject *context`)

Nearly identical to `PyArray_FromAny` (...) except *requirements* can contain `NPY_ARRAY_NOTSWAPPED` (over-riding the specification in *dtype*) and `NPY_ARRAY_ELEMENTSTRIDES` which indicates that the array should be aligned in the sense that the strides are multiples of the element size.

`PyObject *PyArray_FromArray` (*PyArrayObject* *op, *PyArray_Descr* *newtype, int requirements)

Special case of *PyArray_FromAny* for when *op* is already an array but it needs to be of a specific *newtype* (including byte-order) or has certain *requirements*.

`PyObject *PyArray_FromStructInterface` (*PyObject* *op)

Returns an ndarray object from a Python object that exposes the `__array_struct__` attribute and follows the array interface protocol. If the object does not contain this attribute then a borrowed reference to `Py_NotImplemented` is returned.

`PyObject *PyArray_FromInterface` (*PyObject* *op)

Returns an ndarray object from a Python object that exposes the `__array_interface__` attribute following the array interface protocol. If the object does not contain this attribute then a borrowed reference to `Py_NotImplemented` is returned.

`PyObject *PyArray_FromArrayAttr` (*PyObject* *op, *PyArray_Descr* *dtype, *PyObject* *context)

Return an ndarray object from a Python object that exposes the `__array__` method. The third-party implementations of `__array__` must take *dtype* and *copy* keyword arguments. *context* is unused.

`PyObject *PyArray_ContiguousFromAny` (*PyObject* *op, int typenum, int min_depth, int max_depth)

This function returns a (C-style) contiguous and behaved function array from any nested sequence or array interface exporting object, *op*, of (non-flexible) type given by the enumerated *typenum*, of minimum depth *min_depth*, and of maximum depth *max_depth*. Equivalent to a call to *PyArray_FromAny* with requirements set to `NPY_ARRAY_DEFAULT` and the *type_num* member of the *type* argument set to *typenum*.

`PyObject *PyArray_ContiguousFromObject` (*PyObject* *op, int typenum, int min_depth, int max_depth)

This function returns a well-behaved C-style contiguous array from any nested sequence or array-interface exporting object. The minimum number of dimensions the array can have is given by *min_depth* while the maximum is *max_depth*. This is equivalent to call *PyArray_FromAny* with requirements `NPY_ARRAY_DEFAULT` and `NPY_ARRAY_ENSUREARRAY`.

`PyObject *PyArray_FromObject` (*PyObject* *op, int typenum, int min_depth, int max_depth)

Return an aligned and in native-byteorder array from any nested sequence or array-interface exporting object, *op*, of a type given by the enumerated *typenum*. The minimum number of dimensions the array can have is given by *min_depth* while the maximum is *max_depth*. This is equivalent to a call to *PyArray_FromAny* with requirements set to `BEHAVED`.

`PyObject *PyArray_EnsureArray` (*PyObject* *op)

This function **steals a reference** to *op* and makes sure that *op* is a base-class ndarray. It special cases array scalars, but otherwise calls *PyArray_FromAny* (*op*, `NULL`, 0, 0, `NPY_ARRAY_ENSUREARRAY`, `NULL`).

`PyObject *PyArray_FromString` (char *string, *numpy_intp* slen, *PyArray_Descr* *dtype, *numpy_intp* num, char *sep)

Construct a one-dimensional ndarray of a single type from a binary or (ASCII) text *string* of length *slen*. The data-type of the array to-be-created is given by *dtype*. If *num* is -1, then **copy** the entire string and return an appropriately sized array, otherwise, *num* is the number of items to **copy** from the string. If *sep* is `NULL` (or `""`), then interpret the string as bytes of binary data, otherwise convert the sub-strings separated by *sep* to items of data-type *dtype*. Some data-types may not be readable in text mode and an error will be raised if that occurs. All errors return `NULL`.

`PyObject *PyArray_FromFile` (FILE *fp, *PyArray_Descr* *dtype, *numpy_intp* num, char *sep)

Construct a one-dimensional ndarray of a single type from a binary or text file. The open file pointer is *fp*, the data-type of the array to be created is given by *dtype*. This must match the data in the file. If *num* is -1, then read until the end of the file and return an appropriately sized array, otherwise, *num* is the number of items to read. If *sep* is `NULL` (or `""`), then read from the file in binary mode, otherwise read from the file in text mode with *sep* providing the item separator. Some array types cannot be read in text mode in which case an error is raised.

PyObject *PyArray_FromBuffer (PyObject *buf, PyArray_Descr *dtype, npy_intp count, npy_intp offset)

Construct a one-dimensional ndarray of a single type from an object, *buf*, that exports the (single-segment) buffer protocol (or has an attribute `__buffer__` that returns an object that exports the buffer protocol). A writeable buffer will be tried first followed by a read- only buffer. The `NPY_ARRAY_WRITEABLE` flag of the returned array will reflect which one was successful. The data is assumed to start at *offset* bytes from the start of the memory location for the object. The type of the data in the buffer will be interpreted depending on the data- type descriptor, *dtype*. If *count* is negative then it will be determined from the size of the buffer and the requested itemsize, otherwise, *count* represents how many elements should be converted from the buffer.

int PyArray_CopyInto (PyArrayObject *dest, PyArrayObject *src)

Copy from the source array, *src*, into the destination array, *dest*, performing a data-type conversion if necessary. If an error occurs return -1 (otherwise 0). The shape of *src* must be broadcastable to the shape of *dest*. NumPy checks for overlapping memory when copying two arrays.

int PyArray_CopyObject (PyArrayObject *dest, PyObject *src)

Assign an object *src* to a NumPy array *dest* according to array-coercion rules. This is basically identical to `PyArray_FromAny`, but assigns directly to the output array. Returns 0 on success and -1 on failures.

PyArrayObject *PyArray_GETCONTIGUOUS (PyObject *op)

If *op* is already (C-style) contiguous and well-behaved then just return a reference, otherwise return a (contiguous and well-behaved) copy of the array. The parameter *op* must be a (sub-class of an) ndarray and no checking for that is done.

PyObject *PyArray_FROM_O (PyObject *obj)

Convert *obj* to an ndarray. The argument can be any nested sequence or object that exports the array interface. This is a macro form of `PyArray_FromAny` using `NULL`, 0, 0, 0 for the other arguments. Your code must be able to handle any data-type descriptor and any combination of data-flags to use this macro.

PyObject *PyArray_FROM_OF (PyObject *obj, int requirements)

Similar to `PyArray_FROM_O` except it can take an argument of *requirements* indicating properties the resulting array must have. Available requirements that can be enforced are `NPY_ARRAY_C_CONTIGUOUS`, `NPY_ARRAY_F_CONTIGUOUS`, `NPY_ARRAY_ALIGNED`, `NPY_ARRAY_WRITEABLE`, `NPY_ARRAY_NOTSWAPPED`, `NPY_ARRAY_ENSURECOPY`, `NPY_ARRAY_WRITEBACKIFCOPY`, `NPY_ARRAY_FORCECAST`, and `NPY_ARRAY_ENSUREARRAY`. Standard combinations of flags can also be used:

PyObject *PyArray_FROM_OT (PyObject *obj, int typenum)

Similar to `PyArray_FROM_O` except it can take an argument of *typenum* specifying the type-number the returned array.

PyObject *PyArray_FROM_OTF (PyObject *obj, int typenum, int requirements)

Combination of `PyArray_FROM_OF` and `PyArray_FROM_OT` allowing both a *typenum* and a *flags* argument to be provided.

PyObject *PyArray_FROMANY (PyObject *obj, int typenum, int min, int max, int requirements)

Similar to `PyArray_FromAny` except the data-type is specified using a *typenum*. `PyArray_DescrFromType` (*typenum*) is passed directly to `PyArray_FromAny`. This macro also adds `NPY_ARRAY_DEFAULT` to requirements if `NPY_ARRAY_ENSURECOPY` is passed in as requirements.

PyObject *PyArray_CheckAxis (PyObject *obj, int *axis, int requirements)

Encapsulate the functionality of functions and methods that take the *axis=* keyword and work properly with `None` as the axis argument. The input array is *obj*, while **axis* is a converted integer (so that **axis* == `NPY_RAVEL_AXIS` is the `None` value), and *requirements* gives the needed properties of *obj*. The output is a converted version of the input so that requirements are met and if needed a flattening has occurred. On output negative values of **axis* are converted and the new value is checked to ensure consistency with the shape of *obj*.

Dealing with types

General check of Python Type

int **PyArray_Check** (*PyObject* *op)

Evaluates true if *op* is a Python object whose type is a sub-type of *PyArray_Type*.

int **PyArray_CheckExact** (*PyObject* *op)

Evaluates true if *op* is a Python object with type *PyArray_Type*.

int **PyArray_HasArrayInterface** (*PyObject* *op, *PyObject* *out)

If *op* implements any part of the array interface, then *out* will contain a new reference to the newly created ndarray using the interface or *out* will contain NULL if an error during conversion occurs. Otherwise, *out* will contain a borrowed reference to *Py_NotImplemented* and no error condition is set.

int **PyArray_HasArrayInterfaceType** (*PyObject* *op, *PyArray_Descr* *dtype, *PyObject* *context, *PyObject* *out)

If *op* implements any part of the array interface, then *out* will contain a new reference to the newly created ndarray using the interface or *out* will contain NULL if an error during conversion occurs. Otherwise, *out* will contain a borrowed reference to *Py_NotImplemented* and no error condition is set. This version allows setting of the dtype in the part of the array interface that looks for the `__array__` attribute. *context* is unused.

int **PyArray_IsZeroDim** (*PyObject* *op)

Evaluates true if *op* is an instance of (a subclass of) *PyArray_Type* and has 0 dimensions.

PyArray_IsScalar (op, cls)

Evaluates true if *op* is an instance of `Py{cls}ArrType_Type`.

int **PyArray_CheckScalar** (*PyObject* *op)

Evaluates true if *op* is either an array scalar (an instance of a sub-type of *PyGenericArrType_Type*), or an instance of (a sub-class of) *PyArray_Type* whose dimensionality is 0.

int **PyArray_IsPythonNumber** (*PyObject* *op)

Evaluates true if *op* is an instance of a builtin numeric type (int, float, complex, long, bool)

int **PyArray_IsPythonScalar** (*PyObject* *op)

Evaluates true if *op* is a builtin Python scalar object (int, float, complex, bytes, str, long, bool).

int **PyArray_IsAnyScalar** (*PyObject* *op)

Evaluates true if *op* is either a Python scalar object (see *PyArray_IsPythonScalar*) or an array scalar (an instance of a sub-type of *PyGenericArrType_Type*).

int **PyArray_CheckAnyScalar** (*PyObject* *op)

Evaluates true if *op* is a Python scalar object (see *PyArray_IsPythonScalar*), an array scalar (an instance of a sub-type of *PyGenericArrType_Type*) or an instance of a sub-type of *PyArray_Type* whose dimensionality is 0.

Data-type accessors

Some of the descriptor attributes may not always be defined and should or cannot not be accessed directly.

Changed in version 2.0: Prior to NumPy 2.0 the ABI was different but unnecessary large for user DTypes. These accessors were all added in 2.0 and can be backported (see `migration_c_descr`).

numpy_intp **PyDataType_ELSIZE** (*PyArray_Descr* *descr)

The element size of the datatype (`itemsize` in Python).

Note: If the `descr` is attached to an array `PyArray_ITEMSIZE(arr)` can be used and is available on all NumPy versions.

void **PyDataType_SET_ELSIZE** (*PyArray_Descr* *descr, *numpy_intp* size)

Allows setting of the itemsize, this is *only* relevant for string/bytes datatypes as it is the current pattern to define one with a new size.

numpy_intp **PyDataType_ALIGNMENT** (*PyArray_Descr* *descr)

The alignment of the datatype.

PyObject ***PyDataType_METADATA** (*PyArray_Descr* *descr)

The Metadata attached to a dtype, either NULL or a dictionary.

PyObject ***PyDataType_NAMES** (*PyArray_Descr* *descr)

NULL or a tuple of structured field names attached to a dtype.

PyObject ***PyDataType_FIELDS** (*PyArray_Descr* *descr)

NULL, None, or a dict of structured dtype fields, this dict must not be mutated, NumPy may change the way fields are stored in the future.

This is the same dict as returned by `np.dtype.fields`.

NpyAuxData ***PyDataType_C_METADATA** (*PyArray_Descr* *descr)

C-metadata object attached to a descriptor. This accessor should not be needed usually. The C-Metadata field does provide access to the datetime/timedelta time unit information.

PyArray_ArrayDescr ***PyDataType_SUBARRAY** (*PyArray_Descr* *descr)

Information about a subarray dtype equivalent to the Python `np.dtype.base` and `np.dtype.shape`.

If this is non- NULL, then this data-type descriptor is a C-style contiguous array of another data-type descriptor. In other-words, each element that this descriptor describes is actually an array of some other base descriptor. This is most useful as the data-type descriptor for a field in another data-type descriptor. The fields member should be NULL if this is non- NULL (the fields member of the base descriptor can be non- NULL however).

type **PyArray_ArrayDescr**

```
typedef struct {
    PyArray_Descr *base;
    PyObject *shape;
} PyArray_ArrayDescr;
```

PyArray_Descr ***base**

The data-type-descriptor object of the base-type.

PyObject ***shape**

The shape (always C-style contiguous) of the sub-array as a Python tuple.

char **PyDataType_TYPE** (*PyArray_Descr* *descr)

New in version 2.5.

Data type character code. See `numpy.dtype.char`. Only set for built-in and legacy user DTypes. Null character (b'\x00') otherwise.

char **PyDataType_KIND** (*PyArray_Descr* *descr)

New in version 2.5.

Data type kind character code. See `numpy.dtype.kind`. Only set for built-in and legacy user DTypes. Null character (b'\x00') otherwise.

char **PyDataType_BYTEORDER** (*PyArray_Descr* *descr)

New in version 2.5.

Data type bytorder character code. One of '=' (native), '<' (little-endian), '>' (big-endian), or '|' (not applicable). See [numpy.dtype.byteorder](#).

PyObject ***PyDataType_TYPEOBJ** (*PyArray_Descr* *descr)

New in version 2.5.

The type object for the scalar type. See the `typeobj` member of the `PyArray_Descr` struct. See [PyArray_Descr](#) for a full description of the `PyArray_Descr` struct layout.

Data-type checking

For the `typenum` macros, the argument is an integer representing an enumerated array data type. For the array type checking macros the argument must be a `PyObject*` that can be directly interpreted as a `PyArrayObject*`.

int **PyTypeNum_ISUNSIGNED** (int num)

int **PyDataType_ISUNSIGNED** (*PyArray_Descr* *descr)

int **PyArray_ISUNSIGNED** (*PyArrayObject* *obj)

Type represents an unsigned integer.

int **PyTypeNum_ISSIGNED** (int num)

int **PyDataType_ISSIGNED** (*PyArray_Descr* *descr)

int **PyArray_ISSIGNED** (*PyArrayObject* *obj)

Type represents a signed integer.

int **PyTypeNum_ISINTEGER** (int num)

int **PyDataType_ISINTEGER** (*PyArray_Descr* *descr)

int **PyArray_ISINTEGER** (*PyArrayObject* *obj)

Type represents any integer.

int **PyTypeNum_ISFLOAT** (int num)

int **PyDataType_ISFLOAT** (*PyArray_Descr* *descr)

int **PyArray_ISFLOAT** (*PyArrayObject* *obj)

Type represents any floating point number.

int **PyTypeNum_ISCOMPLEX** (int num)

int **PyDataType_ISCOMPLEX** (*PyArray_Descr* *descr)

int **PyArray_ISCOMPLEX** (*PyArrayObject* *obj)

Type represents any complex floating point number.

int **PyTypeNum_ISNUMBER** (int num)

int **PyDataType_ISNUMBER** (*PyArray_Descr* *descr)

int **PyArray_ISNUMBER** (*PyArrayObject* *obj)

Type represents any integer, floating point, or complex floating point number.

int **PyTypeNum_ISSTRING** (int num)

int **PyDataType_ISSTRING** (*PyArray_Descr* *descr)

int **PyArray_ISSTRING** (*PyArrayObject* *obj)

Type represents a string data type.

int **PyTypeNum_ISFLEXIBLE** (int num)

int **PyDataType_ISFLEXIBLE** (*PyArray_Descr* *descr)

int **PyArray_ISFLEXIBLE** (*PyArrayObject* *obj)

Type represents one of the flexible array types (*NPY_STRING*, *NPY_UNICODE*, or *NPY_VOID*).

int **PyDataType_ISUNSIZED** (*PyArray_Descr* *descr)

Type has no size information attached, and can be resized. Should only be called on flexible dtypes. Types that are attached to an array will always be sized, hence the array form of this macro not existing.

For structured datatypes with no fields this function now returns False.

int **PyTypeNum_ISUSERDEF** (int num)

int **PyDataType_ISUSERDEF** (*PyArray_Descr* *descr)

int **PyArray_ISUSERDEF** (*PyArrayObject* *obj)

Type represents a user-defined type.

int **PyTypeNum_ISEXTENDED** (int num)

int **PyDataType_ISEXTENDED** (*PyArray_Descr* *descr)

int **PyArray_ISEXTENDED** (*PyArrayObject* *obj)

Type is either flexible or user-defined.

int **PyTypeNum_ISOBJECT** (int num)

int **PyDataType_ISOBJECT** (*PyArray_Descr* *descr)

int **PyArray_ISOBJECT** (*PyArrayObject* *obj)

Type represents object data type.

int **PyTypeNum_ISBOOL** (int num)

int **PyDataType_ISBOOL** (*PyArray_Descr* *descr)

int **PyArray_ISBOOL** (*PyArrayObject* *obj)

Type represents Boolean data type.

int **PyDataType_HASFIELDS** (*PyArray_Descr* *descr)

int **PyArray_HASFIELDS** (*PyArrayObject* *obj)

Type has fields associated with it.

int **PyArray_ISNOTSWAPPED** (*PyArrayObject* *m)

Evaluates true if the data area of the ndarray *m* is in machine byte-order according to the array's data-type descriptor.

int **PyArray_ISBYTESWAPPED** (*PyArrayObject* *m)

Evaluates true if the data area of the ndarray *m* is **not** in machine byte-order according to the array's data-type descriptor.

numpy_bool **PyArray_EquivTypes** (*PyArray_Descr* *type1, *PyArray_Descr* *type2)

Return *NPY_TRUE* if *type1* and *type2* actually represent equivalent types for this platform (the fortran member of each type is ignored). For example, on 32-bit platforms, *NPY_LONG* and *NPY_INT* are equivalent. Otherwise return *NPY_FALSE*.

numpy_bool **PyArray_EquivArrTypes** (*PyArrayObject* *a1, *PyArrayObject* *a2)

Return *NPY_TRUE* if *a1* and *a2* are arrays with equivalent types for this platform.

numpy_bool **PyArray_EquivTypenums** (int typenum1, int typenum2)

Special case of *PyArray_EquivTypes* (...) that does not accept flexible data types but may be easier to call.

int **PyArray_EquivByteorders** (int b1, int b2)

True if byteorder characters *b1* and *b2* (*NPY_LITTLE*, *NPY_BIG*, *NPY_NATIVE*, *NPY_IGNORE*) are either equal or equivalent as to their specification of a native byte order. Thus, on a little-endian machine *NPY_LITTLE* and *NPY_NATIVE* are equivalent where they are not equivalent on a big-endian machine.

Converting data types

PyObject ***PyArray_Cast** (*PyArrayObject* *arr, int typenum)

Mainly for backwards compatibility to the Numeric C-API and for simple casts to non-flexible types. Return a new array object with the elements of *arr* cast to the data-type *typenum* which must be one of the enumerated types and not a flexible type.

PyObject ***PyArray_CastToType** (*PyArrayObject* *arr, *PyArray_Descr* *type, int fortran)

Return a new array of the *type* specified, casting the elements of *arr* as appropriate. The fortran argument specifies the ordering of the output array.

int **PyArray_CastTo** (*PyArrayObject* *out, *PyArrayObject* *in)

As of 1.6, this function simply calls *PyArray_CopyInto*, which handles the casting.

Cast the elements of the array *in* into the array *out*. The output array should be writeable, have an integer-multiple of the number of elements in the input array (more than one copy can be placed in out), and have a data type that is one of the builtin types. Returns 0 on success and -1 if an error occurs.

int **PyArray_CanCastSafely** (int fromtype, int totype)

Returns non-zero if an array of data type *fromtype* can be cast to an array of data type *totype* without losing information. An exception is that 64-bit integers are allowed to be cast to 64-bit floating point values even though this can lose precision on large integers so as not to proliferate the use of long doubles without explicit requests. Flexible array types are not checked according to their lengths with this function.

int **PyArray_CanCastTo** (*PyArray_Descr* *fromtype, *PyArray_Descr* *totype)

PyArray_CanCastTypeTo supersedes this function in NumPy 1.6 and later.

Equivalent to *PyArray_CanCastTypeTo*(fromtype, totype, *NPY_SAFE_CASTING*).

int **PyArray_CanCastTypeTo** (*PyArray_Descr* *fromtype, *PyArray_Descr* *totype, *NPY_CASTING* casting)

Returns non-zero if an array of data type *fromtype* (which can include flexible types) can be cast safely to an array of data type *totype* (which can include flexible types) according to the casting rule *casting*. For simple types with *NPY_SAFE_CASTING*, this is basically a wrapper around *PyArray_CanCastSafely*, but for flexible types such as strings or unicode, it produces results taking into account their sizes. Integer and float types can only be cast to a string or unicode type using *NPY_SAFE_CASTING* if the string or unicode type is big enough to hold the max value of the integer/float type being cast from.

int **PyArray_CanCastArrayTo** (*PyArrayObject* *arr, *PyArray_Descr* *totype, *NPY_CASTING* casting)

Returns non-zero if *arr* can be cast to *totype* according to the casting rule given in *casting*. If *arr* is an array scalar, its value is taken into account, and non-zero is also returned when the value will not overflow or be truncated to an integer when converting to a smaller type.

PyArray_Descr ***PyArray_MinScalarType** (*PyArrayObject* *arr)

Note: With the adoption of NEP 50 in NumPy 2, this function is not used internally. It is currently provided for backwards compatibility, but expected to be eventually deprecated.

If *arr* is an array, returns its data type descriptor, but if *arr* is an array scalar (has 0 dimensions), it finds the data type of smallest size to which the value may be converted without overflow or truncation to an integer.

This function will not demote complex to float or anything to boolean, but will demote a signed integer to an unsigned integer when the scalar value is positive.

PyArray_Descr ***PyArray_PromoteTypes** (*PyArray_Descr* *type1, *PyArray_Descr* *type2)

Finds the data type of smallest size and kind to which *type1* and *type2* may be safely converted. This function is symmetric and associative. A string or unicode result will be the proper size for storing the max value of the input types converted to a string or unicode.

PyArray_Descr ***PyArray_ResultType** (*numpy_intp* narrs, *PyArrayObject* **arrs, *numpy_intp* ndtypes, *PyArray_Descr* **dtypes)

This applies type promotion to all the input arrays and dtype objects, using the NumPy rules for combining scalars and arrays, to determine the output type for an operation with the given set of operands. This is the same result type that ufuncs produce.

See the documentation of `numpy.result_type` for more detail about the type promotion algorithm.

int **PyArray_ObjectType** (*PyObject* *op, int mintype)

This function is superseded by *PyArray_ResultType*.

This function is useful for determining a common type that two or more arrays can be converted to. It only works for non-flexible array types as no itemsize information is passed. The *mintype* argument represents the minimum type acceptable, and *op* represents the object that will be converted to an array. The return value is the enumerated typenumber that represents the data-type that *op* should have.

PyArrayObject ****PyArray_ConvertToCommonType** (*PyObject* *op, int *n)

The functionality this provides is largely superseded by iterator *NpyIter* introduced in 1.6, with flag *NPY_ITER_COMMON_DTYPE* or with the same dtype parameter for all operands.

Convert a sequence of Python objects contained in *op* to an array of ndarrays each having the same data type. The type is selected in the same way as *PyArray_ResultType*. The length of the sequence is returned in *n*, and an *n*-length array of *PyArrayObject* pointers is the return value (or NULL if an error occurs). The returned array must be freed by the caller of this routine (using *PyDataMem_FREE*) and all the array objects in it DECFREF 'd or a memory-leak will occur. The example template-code below shows a typical usage:

```
mps = PyArray_ConvertToCommonType(obj, &n);
if (mps==NULL) return NULL;
{code}
<before return>
for (i=0; i<n; i++) Py_DECREF (mps[i]);
PyDataMem_FREE (mps);
{return}
```

char ***PyArray_Zero** (*PyArrayObject* *arr)

A pointer to newly created memory of size *arr* ->itemsize that holds the representation of 0 for that type. The returned pointer, *ret*, **must be freed** using *PyDataMem_FREE* (*ret*) when it is not needed anymore.

char ***PyArray_One** (*PyArrayObject* *arr)

A pointer to newly created memory of size *arr* ->itemsize that holds the representation of 1 for that type. The returned pointer, *ret*, **must be freed** using *PyDataMem_FREE* (*ret*) when it is not needed anymore.

int **PyArray_ValidType** (int typenum)

Returns *NPY_TRUE* if *typenum* represents a valid type-number (builtin or user-defined or character code). Otherwise, this function returns *NPY_FALSE*.

User-defined data types

void **PyArray_InitArrFuncs** (*PyArray_ArrFuncs* *f)

Initialize all function pointers and members to NULL.

int **PyArray_RegisterDataType** (*PyArray_DescrProto* *dtype)

Note: As of NumPy 2.0 this API is considered legacy, the new DType API is more powerful and provides additional flexibility. The API may eventually be deprecated but support is continued for the time being.

Compiling for NumPy 1.x and 2.x

NumPy 2.x requires passing in a *PyArray_DescrProto* typed struct rather than a *PyArray_Descr*. This is necessary to allow changes. To allow code to run and compile on both 1.x and 2.x you need to change the type of your struct to *PyArray_DescrProto* and add:

```
/* Allow compiling on NumPy 1.x */
#if NPY_ABI_VERSION < 0x02000000
#define PyArray_DescrProto PyArray_Descr
#endif
```

for 1.x compatibility. Further, the struct will *not* be the actual descriptor anymore, only its type number will be updated. After successful registration, you must thus fetch the actual dtype with:

```
int type_num = PyArray_RegisterDataType(&my_descr_proto);
if (type_num < 0) {
    /* error */
}
PyArray_Descr *my_descr = PyArray_DescrFromType(type_num);
```

With these two changes, the code should compile and work on both 1.x and 2.x or later.

In the unlikely case that you are heap allocating the dtype struct you should free it again on NumPy 2, since a copy is made. The struct is not a valid Python object, so do not use *Py_DECREF* on it.

Transitioning to the new DType API

Users currently using the old DType API may not be able to easily transition due to NumPy issues that would cause regressions. While new DTypes may reasonably limit themselves to newer NumPy versions, existing DTypes cannot do so.

You can transition to the new DType API by using the *NPY_DT_legacy_descriptor_proto* slot when registering. This slot is available when compiling with NumPy 2.5 and provides support for NumPy 2.0 and higher (it can also be vendored to compile on older versions of NumPy).

Register a data-type as a new user-defined data type for arrays. The type must have most of its entries filled in. This is not always checked and errors can produce segfaults. In particular, the *typeobj* member of the *dtype* structure must be filled with a Python type that has a fixed-size element-size that corresponds to the *elsize* member of *dtype*. Also the *f* member must have the required functions: *nonzero*, *copyswap*, *copyswapn*, *getitem*, *setitem*, and *cast* (some of the cast functions may be NULL if no support is desired). To avoid confusion, you should choose a unique character typecode but this is not enforced and not relied on internally.

A user-defined type number is returned that uniquely identifies the type. A pointer to the new structure can then be obtained from *PyArray_DescrFromType* using the returned type number. A -1 is returned if an error

occurs. If this *dtype* has already been registered (checked only by the address of the pointer), then return the previously-assigned type-number.

The number of user DTypes known to numpy is stored in `NPY_NUMUSERTYPES`, a static global variable that is public in the C API. Accessing this symbol is inherently *not* thread-safe. If for some reason you need to use this API in a multithreaded context, you will need to add your own locking, NumPy does not ensure new data types can be added in a thread-safe manner.

int **PyArray_RegisterCastFunc** (*PyArray_Descr* *descr, int totype, *PyArray_VectorUnaryFunc* *castfunc)

Register a low-level casting function, *castfunc*, to convert from the data-type, *descr*, to the given data-type number, *totype*. Any old casting function is over-written. A 0 is returned on success or a -1 on failure.

Note: This function will eventually be deprecated. Please migrate to the new DType API for casts. See [NPY_DT_legacy_descriptor_proto](#) for details.

type **PyArray_VectorUnaryFunc**

The function pointer type for low-level casting functions.

int **PyArray_RegisterCanCast** (*PyArray_Descr* *descr, int totype, *NPY_SCALARKIND* scalar)

Register the data-type number, *totype*, as castable from data-type object, *descr*, of the given *scalar* kind. Use *scalar* = `NPY_NOSCALAR` to register that an array of data-type *descr* can be cast safely to a data-type whose *type_number* is *totype*. The return value is 0 on success or -1 on failure.

Note: This function will eventually be deprecated. Please migrate to the new DType API for casts. See [NPY_DT_legacy_descriptor_proto](#) for details. The new DType API provides more flexibility and speed even for dtypes compatible with the legacy API.

Special functions for NPY_OBJECT

Warning: When working with arrays or buffers filled with objects NumPy tries to ensure such buffers are filled with `None` before any data may be read. However, code paths may exist where an array is only initialized to `NULL`. NumPy itself accepts `NULL` as an alias for `None`, but may `assert non-NULL` when compiled in debug mode.

Because NumPy is not yet consistent about initialization with `None`, users **must** expect a value of `NULL` when working with buffers created by NumPy. Users **should** also ensure to pass fully initialized buffers to NumPy, since NumPy may make this a strong requirement in the future.

There is currently an intention to ensure that NumPy always initializes object arrays before they may be read. Any failure to do so will be regarded as a bug. In the future, users may be able to rely on non-`NULL` values when reading from any array, although exceptions for writing to freshly created arrays may remain (e.g. for output arrays in ufunc code). As of NumPy 1.23 known code paths exist where proper filling is not done.

int **PyArray_INCREF** (*PyArrayObject* *op)

Used for an array, *op*, that contains any Python objects. It increments the reference count of every object in the array according to the data-type of *op*. A -1 is returned if an error occurs, otherwise 0 is returned.

void **PyArray_Item_INCREF** (char *ptr, *PyArray_Descr* *dtype)

A function to INCREMENT all the objects at the location *ptr* according to the data-type *dtype*. If *ptr* is the start of a structured type with an object at any offset, then this will (recursively) increment the reference count of all object-like items in the structured type.

int **PyArray_XDECREF** (*PyArrayObject* *op)

Used for an array, *op*, that contains any Python objects. It decrements the reference count of every object in the array according to the data-type of *op*. Normal return value is 0. A -1 is returned if an error occurs.

void **PyArray_Item_XDECREF** (char *ptr, *PyArray_Descr* *dtype)

A function to XDECREF all the object-like items at the location *ptr* as recorded in the data-type, *dtype*. This works recursively so that if *dtype* itself has fields with data-types that contain object-like items, all the object-like fields will be XDECREF 'd.

int **PyArray_SetWritebackIfCopyBase** (*PyArrayObject* *arr, *PyArrayObject* *base)

Precondition: *arr* is a copy of *base* (though possibly with different strides, ordering, etc.) Sets the `NPY_ARRAY_WRITEBACKIFCOPY` flag and *arr*->*base*, and set *base* to READONLY. Call `PyArray_ResolveWritebackIfCopy` before calling `Py_DECREF` in order to copy any changes back to *base* and reset the READONLY flag.

Returns 0 for success, -1 for failure.

Array flags

The `flags` attribute of the `PyArrayObject` structure contains important information about the memory used by the array (pointed to by the `data` member) This flag information must be kept accurate or strange results and even segfaults may result.

There are 6 (binary) flags that describe the memory area used by the data buffer. These constants are defined in `arrayobject.h` and determine the bit-position of the flag. Python exposes a nice attribute- based interface as well as a dictionary-like interface for getting (and, if appropriate, setting) these flags.

Memory areas of all kinds can be pointed to by an ndarray, necessitating these flags. If you get an arbitrary `PyArrayObject` in C-code, you need to be aware of the flags that are set. If you need to guarantee a certain kind of array (like `NPY_ARRAY_C_CONTIGUOUS` and `NPY_ARRAY_BEHAVED`), then pass these requirements into the `PyArray_FromAny` function.

In versions 1.6 and earlier of NumPy, the following flags did not have the `_ARRAY_` macro namespace in them. That form of the constant names is deprecated in 1.7.

Basic Array Flags

An ndarray can have a data segment that is not a simple contiguous chunk of well-behaved memory you can manipulate. It may not be aligned with word boundaries (very important on some platforms). It might have its data in a different byte-order than the machine recognizes. It might not be writeable. It might be in Fortran-contiguous order. The array flags are used to indicate what can be said about data associated with an array.

NPY_ARRAY_C_CONTIGUOUS

The data area is in C-style contiguous order (last index varies the fastest).

NPY_ARRAY_F_CONTIGUOUS

The data area is in Fortran-style contiguous order (first index varies the fastest).

Note: Arrays can be both C-style and Fortran-style contiguous simultaneously. This is clear for 1-dimensional arrays, but can also be true for higher dimensional arrays.

Even for contiguous arrays a stride for a given dimension `arr.strides[dim]` may be *arbitrary* if `arr.shape[dim] == 1` or the array has no elements. It does *not* generally hold that `self.strides[-1] == self.itemsize` for C-style contiguous arrays or `self.strides[0] == self.itemsize` for Fortran-style contiguous arrays is true. The correct way to access the `itemsize` of an array from the C API is `PyArray_ITEMSIZE(arr)`.

See also:*Internal memory layout of an ndarray***NPY_ARRAY_OWNDATA**

The data area is owned by this array. Should never be set manually, instead create a `PyObject` wrapping the data and set the array's base to that object. For an example, see the test in `test_mem_policy`.

NPY_ARRAY_ALIGNED

The data area and all array elements are aligned appropriately.

NPY_ARRAY_WRITEABLE

The data area can be written to.

Notice that the above 3 flags are defined so that a new, well- behaved array has these flags defined as true.

NPY_ARRAY_WRITEBACKIFCOPY

The data area represents a (well-behaved) copy whose information should be transferred back to the original when `PyArray_ResolveWritebackIfCopy` is called.

This is a special flag that is set if this array represents a copy made because a user required certain flags in `PyArray_FromAny` and a copy had to be made of some other array (and the user asked for this flag to be set in such a situation). The base attribute then points to the “misbehaved” array (which is set `read_only`). `PyArray_ResolveWritebackIfCopy` will copy its contents back to the “misbehaved” array (casting if necessary) and will reset the “misbehaved” array to `NPY_ARRAY_WRITEABLE`. If the “misbehaved” array was not `NPY_ARRAY_WRITEABLE` to begin with then `PyArray_FromAny` would have returned an error because `NPY_ARRAY_WRITEBACKIFCOPY` would not have been possible.

`PyArray_UpdateFlags` (`obj`, `flags`) will update the `obj->flags` for flags which can be any of `NPY_ARRAY_C_CONTIGUOUS`, `NPY_ARRAY_F_CONTIGUOUS`, `NPY_ARRAY_ALIGNED`, or `NPY_ARRAY_WRITEABLE`.

Combinations of array flags**NPY_ARRAY_BEHAVED**

`NPY_ARRAY_ALIGNED` | `NPY_ARRAY_WRITEABLE`

NPY_ARRAY_CARRAY

`NPY_ARRAY_C_CONTIGUOUS` | `NPY_ARRAY_BEHAVED`

NPY_ARRAY_CARRAY_RO

`NPY_ARRAY_C_CONTIGUOUS` | `NPY_ARRAY_ALIGNED`

NPY_ARRAY_FARRAY

`NPY_ARRAY_F_CONTIGUOUS` | `NPY_ARRAY_BEHAVED`

NPY_ARRAY_FARRAY_RO

`NPY_ARRAY_F_CONTIGUOUS` | `NPY_ARRAY_ALIGNED`

NPY_ARRAY_DEFAULT

`NPY_ARRAY_CARRAY`

NPY_ARRAY_IN_ARRAY

`NPY_ARRAY_C_CONTIGUOUS` | `NPY_ARRAY_ALIGNED`

NPY_ARRAY_IN_FARRAY

`NPY_ARRAY_F_CONTIGUOUS` | `NPY_ARRAY_ALIGNED`

NPY_ARRAY_OUT_ARRAY

`NPY_ARRAY_C_CONTIGUOUS` | `NPY_ARRAY_WRITEABLE` | `NPY_ARRAY_ALIGNED`

NPY_ARRAY_OUT_FARRAY

`NPY_ARRAY_F_CONTIGUOUS` | `NPY_ARRAY_WRITEABLE` | `NPY_ARRAY_ALIGNED`

NPY_ARRAY_INOUT_ARRAY

`NPY_ARRAY_C_CONTIGUOUS` | `NPY_ARRAY_WRITEABLE` | `NPY_ARRAY_ALIGNED` |
`NPY_ARRAY_WRITEBACKIFCOPY`

NPY_ARRAY_INOUT_FARRAY

`NPY_ARRAY_F_CONTIGUOUS` | `NPY_ARRAY_WRITEABLE` | `NPY_ARRAY_ALIGNED` |
`NPY_ARRAY_WRITEBACKIFCOPY`

NPY_ARRAY_UPDATE_ALL

`NPY_ARRAY_C_CONTIGUOUS` | `NPY_ARRAY_F_CONTIGUOUS` | `NPY_ARRAY_ALIGNED`

Flag-like constants

These constants are used in `PyArray_FromAny` (and its macro forms) to specify desired properties of the new array.

NPY_ARRAY_FORCECAST

Cast to the desired type, even if it can't be done without losing information.

NPY_ARRAY_ENSURECOPY

Make sure the resulting array is a copy of the original.

NPY_ARRAY_ENSUREARRAY

Make sure the resulting object is an actual ndarray, and not a sub-class.

These constants are used in `PyArray_CheckFromAny` (and its macro forms) to specify desired properties of the new array.

NPY_ARRAY_NOTSWAPPED

Make sure the returned array has a data-type descriptor that is in machine byte-order, over-riding any specification in the `dtype` argument. Normally, the byte-order requirement is determined by the `dtype` argument. If this flag is set and the dtype argument does not indicate a machine byte-order descriptor (or is NULL and the object is already an array with a data-type descriptor that is not in machine byte-order), then a new data-type descriptor is created and used with its byte-order field set to native.

NPY_ARRAY_BEHAVED_NS

`NPY_ARRAY_ALIGNED` | `NPY_ARRAY_WRITEABLE` | `NPY_ARRAY_NOTSWAPPED`

NPY_ARRAY_ELEMENTSTRIDES

Make sure the returned array has strides that are multiples of the element size.

Flag checking

For all of these macros `arr` must be an instance of a (subclass of) `PyArray_Type`.

int **PyArray_CHKFLAGS** (const *PyArrayObject* *arr, int flags)

The first parameter, `arr`, must be an ndarray or subclass. The parameter, `flags`, should be an integer consisting of bitwise combinations of the possible flags an array can have: `NPY_ARRAY_C_CONTIGUOUS`, `NPY_ARRAY_F_CONTIGUOUS`, `NPY_ARRAY_OWNDATA`, `NPY_ARRAY_ALIGNED`, `NPY_ARRAY_WRITEABLE`, `NPY_ARRAY_WRITEBACKIFCOPY`.

int **PyArray_IS_C_CONTIGUOUS** (const *PyArrayObject* *arr)

Evaluates true if `arr` is C-style contiguous.

int **PyArray_IS_F_CONTIGUOUS** (const *PyArrayObject* *arr)

Evaluates true if *arr* is Fortran-style contiguous.

int **PyArray_ISFORTRAN** (const *PyArrayObject* *arr)

Evaluates true if *arr* is Fortran-style contiguous and *not* C-style contiguous. *PyArray_IS_F_CONTIGUOUS* is the correct way to test for Fortran-style contiguity.

int **PyArray_ISWRITEABLE** (const *PyArrayObject* *arr)

Evaluates true if the data area of *arr* can be written to

int **PyArray_ISALIGNED** (const *PyArrayObject* *arr)

Evaluates true if the data area of *arr* is properly aligned on the machine.

int **PyArray_ISBEHAVED** (const *PyArrayObject* *arr)

Evaluates true if the data area of *arr* is aligned and writeable and in machine byte-order according to its descriptor.

int **PyArray_ISBEHAVED_RO** (const *PyArrayObject* *arr)

Evaluates true if the data area of *arr* is aligned and in machine byte-order.

int **PyArray_ISCARRAY** (const *PyArrayObject* *arr)

Evaluates true if the data area of *arr* is C-style contiguous, and *PyArray_ISBEHAVED* (*arr*) is true.

int **PyArray_ISFARRAY** (const *PyArrayObject* *arr)

Evaluates true if the data area of *arr* is Fortran-style contiguous and *PyArray_ISBEHAVED* (*arr*) is true.

int **PyArray_ISCARRAY_RO** (const *PyArrayObject* *arr)

Evaluates true if the data area of *arr* is C-style contiguous, aligned, and in machine byte-order.

int **PyArray_ISFARRAY_RO** (const *PyArrayObject* *arr)

Evaluates true if the data area of *arr* is Fortran-style contiguous, aligned, and in machine byte-order .

int **PyArray_ISONESEGMENT** (const *PyArrayObject* *arr)

Evaluates true if the data area of *arr* consists of a single (C-style or Fortran-style) contiguous segment.

void **PyArray_UpdateFlags** (*PyArrayObject* *arr, int flagmask)

The *NPY_ARRAY_C_CONTIGUOUS*, *NPY_ARRAY_ALIGNED*, and *NPY_ARRAY_F_CONTIGUOUS* array flags can be “calculated” from the array object itself. This routine updates one or more of these flags of *arr* as specified in *flagmask* by performing the required calculation.

Warning: It is important to keep the flags updated (using *PyArray_UpdateFlags* can help) whenever a manipulation with an array is performed that might cause them to change. Later calculations in NumPy that rely on the state of these flags do not repeat the calculation to update them.

int **PyArray_FailUnlessWriteable** (*PyArrayObject* *obj, const char *name)

This function does nothing and returns 0 if *obj* is writeable. It raises an exception and returns -1 if *obj* is not writeable. It may also do other house-keeping, such as issuing warnings on arrays which are transitioning to become views. Always call this function at some point before writing to an array.

name is a name for the array, used to give better error messages. It can be something like “assignment destination”, “output array”, or even just “array”.

ArrayMethod API

ArrayMethod loops are intended as a generic mechanism for writing loops over arrays, including ufunc loops and casts. The public API is defined in the `numpy/dtype_api.h` header. See [PyArrayMethod_Context](#) and [PyArrayMethod_Spec](#) for documentation on the C structs exposed in the ArrayMethod API.

Slots and Typedefs

These are used to identify which kind of function an ArrayMethod slot implements. See [Slots and Typedefs](#) below for documentation on the functions that must be implemented for each slot.

NPY_METH_resolve_descriptors

```
typedef NPY_CASTING (PyArrayMethod_ResolveDescriptors)(struct PyArrayMethodObject_tag *method,  
PyArray_DTypeMeta *const *dtypes, PyArray_Descr *const *given_descrs, PyArray_Descr **loop_descrs, numpy_intp  
*view_offset)
```

The function used to set the descriptors for an operation based on the descriptors of the operands. For example, a ufunc operation with two input operands and one output operand that is called without `out` being set in the python API, `resolve_descriptors` will be passed the descriptors for the two operands and determine the correct descriptor to use for the output based on the output DType set for the ArrayMethod. If `out` is set, then the output descriptor would be passed in as well and should not be overridden.

The *method* is a pointer to the underlying cast or ufunc loop. In the future we may expose this struct publicly but for now this is an opaque pointer and the method cannot be inspected. The *dtypes* is an `nargs` length array of *PyArray_DTypeMeta* pointers, *given_descrs* is an `nargs` length array of input descriptor instances (output descriptors may be NULL if no output was provided by the user), and *loop_descrs* is an `nargs` length array of descriptors that must be filled in by the resolve descriptors implementation. *view_offset* is currently only interesting for casts and can normally be ignored. When a cast does not require any operation, this can be signalled by setting *view_offset* to 0. On error, you must return (*NPY_CASTING*) -1 with an error set.

NPY_METH_strided_loop

NPY_METH_contiguous_loop

NPY_METH_unaligned_strided_loop

NPY_METH_unaligned_contiguous_loop

One dimensional strided loops implementing the behavior (either a ufunc or cast). In most cases, `NPY_METH_strided_loop` is the generic and only version that needs to be implemented. `NPY_METH_contiguous_loop` can be implemented additionally as a more light-weight/faster version and it is used when all inputs and outputs are contiguous.

To deal with possibly unaligned data, NumPy needs to be able to copy unaligned to aligned data. When implementing a new DType, the “cast” or copy for it needs to implement `NPY_METH_unaligned_strided_loop`. Unlike the normal versions, this loop must not assume that the data can be accessed in an aligned fashion. These loops must copy each value before accessing or storing:

```
type_in in_value;  
type_out out_value  
memcpy(&value, in_data, sizeof(type_in));  
out_value = in_value;  
memcpy(out_data, &out_value, sizeof(type_out))
```

while a normal loop can just use:

```
*(type_out *)out_data = *(type_in)in_data;
```

The unaligned loops are currently only used in casts and will never be picked in ufuncs (ufuncs create a temporary copy to ensure aligned inputs). These slot IDs are ignored when `NPY_METH_get_loop` is defined, where instead whichever loop returned by the `get_loop` function is used.

NPY_METH_contiguous_indexed_loop

A specialized inner-loop option to speed up common `ufunc.at` computations.

```
typedef int (PyArrayMethod_StridedLoop)(PyArrayMethod_Context *context, char *const *data, const
    npy_intp *dimensions, const npy_intp *strides, NpyAuxData *auxdata)
```

An implementation of an ArrayMethod loop. All of the loop slot IDs listed above must provide a `PyArrayMethod_StridedLoop` implementation. The *context* is a struct containing context for the loop operation - in particular the input descriptors. The *data* are an array of pointers to the beginning of the input and output array buffers. The *dimensions* are the loop dimensions for the operation. The *strides* are an `nargs` length array of strides for each input. The *auxdata* is an optional set of auxiliary data that can be passed in to the loop - helpful to turn on and off optional behavior or reduce boilerplate by allowing similar ufuncs to share loop implementations or to allocate space that is persistent over multiple strided loop calls.

NPY_METH_get_loop

Allows more fine-grained control over loop selection. Accepts an implementation of `PyArrayMethod_GetLoop`, which in turn returns a strided loop implementation. If `NPY_METH_get_loop` is defined, the other loop slot IDs are ignored, if specified.

```
typedef int (PyArrayMethod_GetLoop)(PyArrayMethod_Context *context, int aligned, int move_references, const
    npy_intp *strides, PyArrayMethod_StridedLoop **out_loop, NpyAuxData **out_transferdata,
    NPY_ARRAYMETHOD_FLAGS *flags);
```

Sets the loop to use for an operation at runtime. The *context* is the runtime context for the operation. *aligned* indicates whether the data access for the loop is aligned (1) or unaligned (0). *move_references* indicates whether embedded references in the data should be copied. *strides* are the strides for the input array, *out_loop* is a pointer that must be filled in with a pointer to the loop implementation. *out_transferdata* can be optionally filled in to allow passing in extra user-defined context to an operation. *flags* must be filled in with ArrayMethod flags relevant for the operation. This is for example necessary to indicate if the inner loop requires the Python GIL to be held.

NPY_METH_get_reduction_initial

```
typedef int (PyArrayMethod_GetReductionInitial)(PyArrayMethod_Context *context, npy_bool
    reduction_is_empty, char *initial)
```

Query an ArrayMethod for the initial value for use in reduction. The *context* is the ArrayMethod context, mainly to access the input descriptors. *reduction_is_empty* indicates whether the reduction is empty. When it is, the value returned may differ. In this case it is a “default” value that may differ from the “identity” value normally used. For example:

- `0.0` is the default for `sum([])`. But `-0.0` is the correct identity otherwise as it preserves the sign for `sum([-0.0])`.
- We use no identity for object, but return the default of `0` and `1` for the empty `sum([], dtype=np.object_)` and `prod([], dtype=np.object_)`. This allows `np.sum(np.array(["a", "b"], dtype=np.object_))` to work.
- `-inf` or `INT_MIN` for `max` is an identity, but at least `INT_MIN` not a good *default* when there are no items.

initial is a pointer to the data for the initial value, which should be filled in. Returns `-1`, `0`, or `1` indicating error, no initial value, and the initial value being successfully filled. Errors must not be given when no initial value is correct, since NumPy may call this even when it is not strictly necessary to do so.

Flags

enum **NPY_ARRAYMETHOD_FLAGS**

These flags allow switching on and off custom runtime behavior for ArrayMethod loops. For example, if a ufunc cannot possibly trigger floating point errors, then the `NPY_METH_NO_FLOATINGPOINT_ERRORS` flag should be set on the ufunc when it is registered.

enumerator **NPY_METH_REQUIRES_PYAPI**

Indicates the method must hold the GIL. If this flag is not set, the GIL is released before the loop is called.

enumerator **NPY_METH_NO_FLOATINGPOINT_ERRORS**

Indicates the method cannot generate floating errors, so checking for floating errors after the loop completes can be skipped.

enumerator **NPY_METH_SUPPORTS_UNALIGNED**

Indicates the method supports unaligned access.

enumerator **NPY_METH_IS_REORDERABLE**

Indicates that the result of applying the loop repeatedly (for example, in a reduction operation) does not depend on the order of application.

enumerator **NPY_METH_RUNTIME_FLAGS**

The flags that can be changed at runtime.

Typedefs

Typedefs for functions that users of the ArrayMethod API can implement are described below.

typedef int (**PyArrayMethod_TraverseLoop**)(void *traverse_context, const *PyArray_Descr* *descr, char *data, *npy_intp* size, *npy_intp* stride, *NpyAuxData* *auxdata)

A traverse loop working on a single array. This is similar to the general strided-loop function. This is designed for loops that need to visit every element of a single array.

Currently this is used for array clearing, via the `NPY_DT_get_clear_loop` DType API hook, and zero-filling, via the `NPY_DT_get_fill_zero_loop` DType API hook. These are most useful for handling arrays storing embedded references to python objects or heap-allocated data.

The *descr* is the descriptor for the array, *data* is a pointer to the array buffer, *size* is the 1D size of the array buffer, *stride* is the stride, and *auxdata* is optional extra data for the loop.

The *traverse_context* is passed in because we may need to pass in Interpreter state or similar in the future, but we don't want to pass in a full context (with pointers to dtypes, method, caller which all make no sense for a traverse function). We assume for now that this context can be just passed through in the future (for structured dtypes).

typedef int (**PyArrayMethod_GetTraverseLoop**)(void *traverse_context, const *PyArray_Descr* *descr, int aligned, *npy_intp* fixed_stride, *PyArrayMethod_TraverseLoop* **out_loop, *NpyAuxData* **out_auxdata, *NPY_ARRAYMETHOD_FLAGS* *flags)

Simplified `get_loop` function specific to dtype traversal

It should set the flags needed for the traversal loop and set *out_loop* to the loop function, which must be a valid `PyArrayMethod_TraverseLoop` pointer. Currently this is used for zero-filling and clearing arrays storing embedded references.

API Functions and Typedefs

These functions are part of the main numpy array API and were added along with the rest of the ArrayMethod API.

int **PyUFunc_AddLoopFromSpec** (*PyObject* *ufunc, *PyArrayMethod_Spec* *spec)

Add loop directly to a ufunc from a given ArrayMethod spec. the main ufunc registration function. This adds a new implementation/loop to a ufunc. It replaces *PyUFunc_RegisterLoopForType*.

type **PyUFunc_LoopSlot**

Structure used to add multiple loops to ufuncs from ArrayMethod specs. This is used in *PyUFunc_AddLoopsFromSpecs*.

```
struct PyUFunc_LoopSlot
```

```
    const char *name
```

The name of the ufunc to add the loop to, in the form like that of entry points, (module ':'?) (object '.')* name, with numpy the default module. Examples: *sin*, *strings.str_len*, *numpy.strings.str_len*. Note that some names are supported but do not directly correspond to ufuncs: "sort", "argsort", "real", "imag". (These do use ufunc-like or even ufuncs internally.)

```
    PyArrayMethod_Spec *spec
```

The ArrayMethod spec to use to create the loop.

int **PyUFunc_AddLoopsFromSpecs** (*PyUFunc_LoopSlot* *slots)

New in version 2.4.

Add multiple loops to ufuncs from ArrayMethod specs. This also handles the registration of methods for the ufunc-like functions *sort* and *argsort* (see [Sorting and Argsorting](#) for details), as well as for the array attributes *.real* and *.imag* needed for user defined complex DTypes (with "real" and "imag" as names).

The *slots* argument must be a NULL-terminated array of *PyUFunc_LoopSlot* (see above), which give the name of the ufunc and spec needed to create the loop.

int **PyUFunc_AddPromoter** (*PyObject* *ufunc, *PyObject* *DType_tuple, *PyObject* *promoter)

Note that currently the output dtypes are always NULL unless they are also part of the signature. This is an implementation detail and could change in the future. However, in general promoters should not have a need for output dtypes. Register a new promoter for a ufunc. The first argument is the ufunc to register the promoter with. The second argument is a Python tuple containing DTypes or None matching the number of inputs and outputs for the ufuncs. The last argument is a promoter is a function stored in a PyCapsule. It is passed the operation and requested DType signatures and can mutate it to attempt a new search for a matching loop/promoter.

typedef int (**PyArrayMethod_PromoterFunction**)(*PyObject* *ufunc, *PyArray_DTypeMeta* *const op_dtypes[], *PyArray_DTypeMeta* *const signature[], *PyArray_DTypeMeta* *new_op_dtypes[])

Type of the promoter function, which must be wrapped into a PyCapsule with name "numpy._ufunc_promoter". It is passed the operation and requested DType signatures and can mutate the signatures to attempt a search for a new loop or promoter that can accomplish the operation by casting the inputs to the "promoted" DTypes.

A promoter should honor *signature[]* (if set). A promoter must return -1 on failure. A Python error may be set but is not required (a general error is set in either paths, although the original error is chained). A promoter must return 0 or 1 on success. NumPy normally checks that *new_op_dtypes* are different from *op_dtypes* to prevent recursion. This check is skipped if the promoter returns 1, which allows the promoter to add a new loop (when adding a new loop, *new_op_dtypes* should be identical to *op_dtypes*).

Changed in version 2.5: After 2.5 a return of 1 indicates that the promoter was successful skipping a recursion protection step. This mainly allows the promoter to add new loop to the ufunc that must now

match instead of the promoter itself. (Normally, a promoter must modify the DTypes help find the right loop.)

int **PyUFunc_GiveFloatingpointErrors** (const char *name, int fpe_errors)

Checks for a floating point error after performing a floating point operation in a manner that takes into account the error signaling configured via `numpy.errstate`. Takes the name of the operation to use in the error message and an integer flag that is one of `NPY_FPE_DIVIDEBYZERO`, `NPY_FPE_OVERFLOW`, `NPY_FPE_UNDERFLOW`, `NPY_FPE_INVALID` to indicate which error to check for.

Returns -1 on failure (an error was raised) and 0 on success.

int **PyUFunc_AddWrappingLoop** (PyObject *ufunc_obj, *PyArray_DTypeMeta* *new_dtypes[],
PyArray_DTypeMeta *wrapped_dtypes[],
PyArrayMethod_TranslateGivenDescriptors *translate_given_descrs,
PyArrayMethod_TranslateLoopDescriptors *translate_loop_descrs)

Allows creating of a fairly lightweight wrapper around an existing ufunc loop. The idea is mainly for units, as this is currently slightly limited in that it enforces that you cannot use a loop from another ufunc.

typedef int (**PyArrayMethod_TranslateGivenDescriptors**)(int nin, int nout, *PyArray_DTypeMeta*
 *wrapped_dtypes[], *PyArray_Descr* *given_descrs[], *PyArray_Descr* *new_descrs[]);

The function to convert the given descriptors (passed in to `resolve_descriptors`) and translates them for the wrapped loop. The new descriptors MUST be viewable with the old ones, `NULL` must be supported (for output arguments) and should normally be forwarded.

The output of of this function will be used to construct views of the arguments as if they were the translated dtypes and does not use a cast. This means this mechanism is mostly useful for DTypes that “wrap” another DType implementation. For example, a unit DType could use this to wrap an existing floating point DType without needing to re-implement low-level ufunc logic. In the unit example, `resolve_descriptors` would handle computing the output unit from the input unit.

typedef int (**PyArrayMethod_TranslateLoopDescriptors**)(int nin, int nout, *PyArray_DTypeMeta*
 *new_dtypes[], *PyArray_Descr* *given_descrs[], *PyArray_Descr* *original_descrs[], *PyArray_Descr* *loop_descrs[]);

The function to convert the actual loop descriptors (as returned by the original `resolve_descriptors` function) to the ones the output array should use. This function must return “viewable” types, it must not mutate them in any form that would break the inner-loop logic. Does not need to support `NULL`.

Wrapping Loop Example

Suppose you want to wrap the `float64` multiply implementation for a `WrappedDoubleDType`. You would add a wrapping loop like so:

```
PyArray_DTypeMeta *orig_dtypes[3] = {
    &WrappedDoubleDType, &WrappedDoubleDType, &WrappedDoubleDType};
PyArray_DTypeMeta *wrapped_dtypes[3] = {
    &PyArray_Float64DType, &PyArray_Float64DType, &PyArray_Float64DType}

PyObject *mod = PyImport_ImportModule("numpy");
if (mod == NULL) {
    return -1;
}
PyObject *multiply = PyObject_GetAttrString(mod, "multiply");
Py_DECREF(mod);

if (multiply == NULL) {
    return -1;
}
```

(continues on next page)

(continued from previous page)

```

}

int res = PyUFunc_AddWrappingLoop(
    multiply, orig_dtypes, wrapped_dtypes, &translate_given_descrs
    &translate_loop_descrs);

Py_DECREF(multiply);

```

Note that this also requires two functions to be defined above this code:

```

static int
translate_given_descrs(int nin, int nout,
                      PyArray_DTypeMeta *NPY_UNUSED(wrapped_dtypes[]),
                      PyArray_Descr *given_descrs[],
                      PyArray_Descr *new_descrs[])
{
    for (int i = 0; i < nin + nout; i++) {
        if (given_descrs[i] == NULL) {
            new_descrs[i] = NULL;
        }
        else {
            new_descrs[i] = PyArray_DescrFromType(NPY_DOUBLE);
        }
    }
    return 0;
}

static int
translate_loop_descrs(int nin, int NPY_UNUSED(nout),
                     PyArray_DTypeMeta *NPY_UNUSED(new_dtypes[]),
                     PyArray_Descr *given_descrs[],
                     PyArray_Descr *original_descrs[],
                     PyArray_Descr *loop_descrs[])
{
    // more complicated parametric DTypes may need to
    // to do additional checking, but we know the wrapped
    // DTypes *have* to be float64 for this example.
    loop_descrs[0] = PyArray_DescrFromType(NPY_FLOAT64);
    Py_INCREF(loop_descrs[0]);
    loop_descrs[1] = PyArray_DescrFromType(NPY_FLOAT64);
    Py_INCREF(loop_descrs[1]);
    loop_descrs[2] = PyArray_DescrFromType(NPY_FLOAT64);
    Py_INCREF(loop_descrs[2]);
}

```

Sorting and Argsorting

Sorting and argsorting methods for dtypes can be registered using the `ArrayMethod` API. This is done by adding an `ArrayMethod` spec with the name "sort" or "argsort" respectively. The spec must have `nin=1` and `nout=1` for both sort and argsort. Sorting is inplace, hence we enforce that `data[0] == data[1]`. Argsorting returns a new array of indices, so the output must be of `NPY_INTp` type.

The context passed to the loop contains the `parameters` field which for these operations is a `PyArrayMethod_SortParameters` * struct. This struct contains a `flags` field which is a bitwise OR of `NPY_SORTKIND` values indicating the kind of sort to perform (that is, whether it is a stable and/or descending sort). If the strided loop depends on the flags, a good way to deal with this is to define `NPY_METH_get_loop`, and not set any of the other loop slots.

struct **PyArrayMethod_SortParameters**

NPY_SORTKIND flags

The flags passed to the sort operation. This is a bitwise OR of *NPY_SORTKIND* values indicating the kind of sort to perform.

These specs can be registered using *PyUFunc_AddLoopsFromSpecs* along with other ufunc loops.

API for calling array methods

Conversion

PyObject **PyArray_GetField* (*PyArrayObject* *self, *PyArray_Descr* *dtype, int offset)

Equivalent to *ndarray.getfield(self, dtype, offset)*. This function steals a reference to *PyArray_Descr* and returns a new array of the given *dtype* using the data in the current array at a specified *offset* in bytes. The *offset* plus the itemsize of the new array type must be less than *self->descr->elsize* or an error is raised. The same shape and strides as the original array are used. Therefore, this function has the effect of returning a field from a structured array. But, it can also be used to select specific bytes or groups of bytes from any array type.

int **PyArray_SetField** (*PyArrayObject* *self, *PyArray_Descr* *dtype, int offset, *PyObject* *val)

Equivalent to *ndarray.setfield(self, val, dtype, offset)*. Set the field starting at *offset* in bytes and of the given *dtype* to *val*. The *offset* plus *dtype->elsize* must be less than *self->descr->elsize* or an error is raised. Otherwise, the *val* argument is converted to an array and copied into the field pointed to. If necessary, the elements of *val* are repeated to fill the destination array. But, the number of elements in the destination must be an integer multiple of the number of elements in *val*.

PyObject **PyArray_Byteswap* (*PyArrayObject* *self, *numpy_bool* inplace)

Equivalent to *ndarray.byteswap(self, inplace)*. Return an array whose data area is byteswapped. If *inplace* is non-zero, then do the byteswap inplace and return a reference to self. Otherwise, create a byteswapped copy and leave self unchanged.

PyObject **PyArray_NewCopy* (*PyArrayObject* *old, *NPY_ORDER* order)

Equivalent to *ndarray.copy(self, fortran)*. Make a copy of the *old* array. The returned array is always aligned and writable with data interpreted the same as the old array. If *order* is *NPY_CORDER*, then a C-style contiguous array is returned. If *order* is *NPY_FORTRANORDER*, then a Fortran-style contiguous array is returned. If *order* is *NPY_ANYORDER*, then the array returned is Fortran-style contiguous only if the old one is; otherwise, it is C-style contiguous.

PyObject **PyArray_ToList* (*PyArrayObject* *self)

Equivalent to *ndarray.tolist(self)*. Return a nested Python list from *self*.

PyObject **PyArray_ToString* (*PyArrayObject* *self, *NPY_ORDER* order)

Equivalent to *ndarray.tobytes(self, order)*. Return the bytes of this array in a Python string.

PyObject **PyArray_ToFile* (*PyArrayObject* *self, FILE *fp, char *sep, char *format)

Write the contents of *self* to the file pointer *fp* in C-style contiguous fashion. Write the data as binary bytes if *sep* is the string "" or NULL. Otherwise, write the contents of *self* as text using the *sep* string as the item separator. Each item will be printed to the file. If the *format* string is not NULL or "", then it is a Python print statement format string showing how the items are to be written.

int **PyArray_Dump** (*PyObject* *self, *PyObject* *file, int protocol)

Pickle the object in *self* to the given *file* (either a string or a Python file object). If *file* is a Python string it is considered to be the name of a file which is then opened in binary mode. The given *protocol* is used (if *protocol* is negative, or the highest available is used). This is a simple wrapper around *cPickle.dump(self, file, protocol)*.

`PyObject *PyArray_Dumps (PyObject *self, int protocol)`

Pickle the object in *self* to a Python string and return it. Use the Pickle *protocol* provided (or the highest available if *protocol* is negative).

`int PyArray_FillWithScalar (PyArrayObject *arr, PyObject *obj)`

Fill the array, *arr*, with the given scalar object, *obj*. The object is first converted to the data type of *arr*, and then copied into every location. A -1 is returned if an error occurs, otherwise 0 is returned.

`PyObject *PyArray_View (PyArrayObject *self, PyArray_Descr *dtype, PyTypeObject *ptype)`

Equivalent to `ndarray.view(self, dtype)`. Return a new view of the array *self* as possibly a different data-type, *dtype*, and different array subclass *ptype*.

If *dtype* is NULL, then the returned array will have the same data type as *self*. The new data-type must be consistent with the size of *self*. Either the itemsizes must be identical, or *self* must be single-segment and the total number of bytes must be the same. In the latter case the dimensions of the returned array will be altered in the last (or first for Fortran-style contiguous arrays) dimension. The data area of the returned array and *self* is exactly the same.

Shape Manipulation

`PyObject *PyArray_Newshape (PyArrayObject *self, PyArray_Dims *newshape, NPY_ORDER order)`

Result will be a new array (pointing to the same memory location as *self* if possible), but having a shape given by *newshape*. If the new shape is not compatible with the strides of *self*, then a copy of the array with the new specified shape will be returned.

`PyObject *PyArray_Reshape (PyArrayObject *self, PyObject *shape)`

Equivalent to `ndarray.reshape(self, shape)` where *shape* is a sequence. Converts *shape* to a `PyArray_Dims` structure and calls `PyArray_Newshape` internally. For back-ward compatibility – Not recommended

`PyObject *PyArray_Squeeze (PyArrayObject *self)`

Equivalent to `ndarray.squeeze(self)`. Return a new view of *self* with all of the dimensions of length 1 removed from the shape.

Warning: matrix objects are always 2-dimensional. Therefore, `PyArray_Squeeze` has no effect on arrays of matrix sub-class.

`PyObject *PyArray_SwapAxes (PyArrayObject *self, int a1, int a2)`

Equivalent to `ndarray.swapaxes(self, a1, a2)`. The returned array is a new view of the data in *self* with the given axes, *a1* and *a2*, swapped.

`PyObject *PyArray_Resize (PyArrayObject *self, PyArray_Dims *newshape, int refcheck, NPY_ORDER fortran)`

Equivalent to `ndarray.resize(self, newshape, refcheck)`. This function only works on single-segment arrays. It changes the shape of *self* in-place and will reallocate the memory for *self* if *newshape* has a different total number of elements than the old shape. If reallocation is necessary, then *self* must own its data, have *self* ->base==NULL, have *self* ->weakrefs==NULL, and (unless *refcheck* is 0) not be referenced by any other array. The *fortran* argument has no effect.

On Python 3.13 and older, the check allows uniquely referenced objects and objects with exactly one reference to be reallocated in-place. On Python 3.14 and newer, the array must be uniquely referenced. See the Python 3.14 [What's New](#) entry on this topic for more information on why there is a behavior difference.

Reallocating arrays in-place can often lead to memory fragmentation and should be avoided. If the goal is to reclaim over-allocated memory, alternatives are to create a view or a copy of just the desired data, or using two passes to build the array: one to cheaply determine the shape and another to allocate and fill. Benchmark your use case to determine what is optimum. You may be surprised to find `resize` actually slows down or bloats your application.

Returns None on success and NULL on error.

PyObject *PyArray_Transpose (*PyArrayObject* *self, *PyArray_Dims* *permute)

Equivalent to `ndarray.transpose(self, permute)`. Permute the axes of the ndarray object *self* according to the data structure *permute* and return the result. If *permute* is NULL, then the resulting array has its axes reversed. For example if *self* has shape $10 \times 20 \times 30$, and *permute* .ptr is (0,2,1) the shape of the result is $10 \times 30 \times 20$. If *permute* is NULL, the shape of the result is $30 \times 20 \times 10$.

PyObject *PyArray_Flatten (*PyArrayObject* *self, *NPY_ORDER* order)

Equivalent to `ndarray.flatten(self, order)`. Return a 1-d copy of the array. If *order* is *NPY_FORTRANORDER* the elements are scanned out in Fortran order (first-dimension varies the fastest). If *order* is *NPY_CORDER*, the elements of *self* are scanned in C-order (last dimension varies the fastest). If *order* is *NPY_ANYORDER*, then the result of `PyArray_ISFORTRAN(self)` is used to determine which order to flatten.

PyObject *PyArray_Ravel (*PyArrayObject* *self, *NPY_ORDER* order)

Equivalent to `self.ravel(order)`. Same basic functionality as `PyArray_Flatten(self, order)` except if *order* is 0 and *self* is C-style contiguous, the shape is altered but no copy is performed.

Item selection and manipulation

PyObject *PyArray_TakeFrom (*PyArrayObject* *self, PyObject *indices, int axis, *PyArrayObject* *ret, *NPY_CLIPMODE* clipmode)

Equivalent to `ndarray.take(self, indices, axis, ret, clipmode)` except *axis* =None in Python is obtained by setting *axis* = *NPY_MAXDIMS* in C. Extract the items from *self* indicated by the integer-valued *indices* along the given *axis*. The clipmode argument can be *NPY_RAISE*, *NPY_WRAP*, or *NPY_CLIP* to indicate what to do with out-of-bound indices. The *ret* argument can specify an output array rather than having one created internally.

PyObject *PyArray_PutTo (*PyArrayObject* *self, PyObject *values, PyObject *indices, *NPY_CLIPMODE* clipmode)

Equivalent to `self.put(values, indices, clipmode)`. Put *values* into *self* at the corresponding (flattened) *indices*. If *values* is too small it will be repeated as necessary.

PyObject *PyArray_PutMask (*PyArrayObject* *self, PyObject *values, PyObject *mask)

Place the *values* in *self* wherever corresponding positions (using a flattened context) in *mask* are true. The *mask* and *self* arrays must have the same total number of elements. If *values* is too small, it will be repeated as necessary.

PyObject *PyArray_Repeat (*PyArrayObject* *self, PyObject *op, int axis)

Equivalent to `ndarray.repeat(self, op, axis)`. Copy the elements of *self*, *op* times along the given *axis*. Either *op* is a scalar integer or a sequence of length *self* ->dimensions[*axis*] indicating how many times to repeat each item along the axis.

PyObject *PyArray_Choose (*PyArrayObject* *self, PyObject *op, *PyArrayObject* *ret, *NPY_CLIPMODE* clipmode)

Equivalent to `ndarray.choose(self, op, ret, clipmode)`. Create a new array by selecting elements from the sequence of arrays in *op* based on the integer values in *self*. The arrays must all be broadcastable to the same shape and the entries in *self* should be between 0 and len(*op*). The output is placed in *ret* unless it is NULL in which case a new output is created. The *clipmode* argument determines behavior for when entries in *self* are not between 0 and len(*op*).

NPY_RAISE

raise a ValueError;

NPY_WRAP

wrap values < 0 by adding len(*op*) and values >=len(*op*) by subtracting len(*op*) until they are in range;

NPY_CLIP

all values are clipped to the region `[0, len(op) )`.

PyObject *PyArray_Sort (*PyArrayObject* *self, int axis, *NPY_SORTKIND* kind)

Return an array with the items of *self* sorted along *axis*. The array is sorted using an algorithm whose properties are specified by the value of *kind*, an integer/enum specifying the requirements of the sorting algorithm used. If *self*→*descr* is a data-type with fields defined, then *self*→*descr*→*names* is used to determine the sort order. A comparison where the first field is equal will use the second field and so on. To alter the sort order of a structured array, create a new data-type with a different order of names and construct a view of the array with that new data-type.

This is the C level function called by the ndarray method `ndarray.sort`, though with a different meaning of *kind* – see *NPY_SORTKIND* below.

PyObject *PyArray_ArgSort (*PyArrayObject* *self, int axis, *NPY_SORTKIND* kind)

Return an array of indices such that selection of these indices along the given *axis* would return a sorted version of *self*. The array is sorted using an algorithm whose properties are specified by *kind*, an integer/enum specifying the requirements of the sorting algorithm used. If *self*→*descr* is a data-type with fields defined, then *self*→*descr*→*names* is used to determine the sort order. A comparison where the first field is equal will use the second field and so on. To alter the sort order of a structured array, create a new data-type with a different order of names and construct a view of the array with that new data-type.

This is the C level function called by the ndarray method `ndarray.argsort`, though with a different meaning of *kind* – see *NPY_SORTKIND* below.

PyObject *PyArray_LexSort (*PyObject* *sort_keys, int axis)

Given a sequence of arrays (*sort_keys*) of the same shape, return an array of indices (similar to `PyArray_ArgSort(...)`) that would sort the arrays lexicographically. A lexicographic sort specifies that when two keys are found to be equal, the order is based on comparison of subsequent keys. A merge sort (which leaves equal entries unmoved) is required to be defined for the types. The sort is accomplished by sorting the indices first using the first *sort_key* and then using the second *sort_key* and so forth. This is equivalent to the `lexsort(sort_keys, axis)` Python command. Because of the way the merge-sort works, be sure to understand the order the *sort_keys* must be in (reversed from the order you would use when comparing two elements).

If these arrays are all collected in a structured array, then `PyArray_Sort(...)` can also be used to sort the array directly.

PyObject *PyArray_SearchSorted (*PyArrayObject* *self, *PyObject* *values, *NPY_SEARCHSIDE* side, *PyObject* *perm)

Equivalent to `ndarray.searchsorted(self, values, side, perm)`. Assuming *self* is a 1-d array in ascending order, then the output is an array of indices the same shape as *values* such that, if the elements in *values* were inserted before the indices, the order of *self* would be preserved. No checking is done on whether or not *self* is in ascending order.

The *side* argument indicates whether the index returned should be that of the first suitable location (if *NPY_SEARCHLEFT*) or of the last (if *NPY_SEARCHRIGHT*).

The *sorter* argument, if not NULL, must be a 1D array of integer indices the same length as *self*, that sorts it into ascending order. This is typically the result of a call to `PyArray_ArgSort(...)`. Binary search is used to find the required insertion points.

int PyArray_Partition (*PyArrayObject* *self, *PyArrayObject* *ktharray, int axis, *NPY_SELECTKIND* which)

Equivalent to `ndarray.partition(self, ktharray, axis, kind)`. Partitions the array so that the values of the element indexed by *ktharray* are in the positions they would be if the array is fully sorted and places all elements smaller than the *kth* before and all elements equal or greater after the *kth* element. The ordering of all elements within the partitions is undefined. If *self*→*descr* is a data-type with fields defined, then *self*→*descr*→*names* is used to determine the sort order. A comparison where the first field is equal will use the second field and so on. To alter

the sort order of a structured array, create a new data-type with a different order of names and construct a view of the array with that new data-type. Returns zero on success and -1 on failure.

PyObject *PyArray_ArgPartition (*PyArrayObject* *op, *PyArrayObject* *ktharray, int axis, *NPY_SELECTKIND* which)

Equivalent to `ndarray.argpartition(self, ktharray, axis, kind)`. Return an array of indices such that selection of these indices along the given *axis* would return a partitioned version of *self*.

PyObject *PyArray_Diagonal (*PyArrayObject* *self, int offset, int axis1, int axis2)

Equivalent to `ndarray.diagonal(self, offset, axis1, axis2)`. Return the *offset* diagonals of the 2-d arrays defined by *axis1* and *axis2*.

numpy_intp **PyArray_CountNonzero** (*PyArrayObject* *self)

Counts the number of non-zero elements in the array object *self*.

PyObject *PyArray_Nonzero (*PyArrayObject* *self)

Equivalent to `ndarray.nonzero(self)`. Returns a tuple of index arrays that select elements of *self* that are nonzero. If `(nd=PyArray_NDIM(self))==1`, then a single index array is returned. The index arrays have data type *NPY_INTP*. If a tuple is returned (`nd != 1`), then its length is *nd*.

PyObject *PyArray_Compress (*PyArrayObject* *self, PyObject *condition, int axis, *PyArrayObject* *out)

Equivalent to `ndarray.compress(self, condition, axis)`. Return the elements along *axis* corresponding to elements of *condition* that are true.

Calculation

Tip: Pass in *NPY_RAVEL_AXIS* for axis in order to achieve the same effect that is obtained by passing in `axis=None` in Python (treating the array as a 1-d array).

Note: The out argument specifies where to place the result. If out is NULL, then the output array is created, otherwise the output is placed in out which must be the correct size and type. A new reference to the output array is always returned even when out is not NULL. The caller of the routine has the responsibility to `Py_DECREF` out if not NULL or a memory-leak will occur.

PyObject *PyArray_ArgMax (*PyArrayObject* *self, int axis, *PyArrayObject* *out)

Equivalent to `ndarray.argmax(self, axis)`. Return the index of the largest element of *self* along *axis*.

PyObject *PyArray_ArgMin (*PyArrayObject* *self, int axis, *PyArrayObject* *out)

Equivalent to `ndarray.argmin(self, axis)`. Return the index of the smallest element of *self* along *axis*.

PyObject *PyArray_Max (*PyArrayObject* *self, int axis, *PyArrayObject* *out)

Equivalent to `ndarray.max(self, axis)`. Returns the largest element of *self* along the given *axis*. When the result is a single element, returns a numpy scalar instead of an ndarray.

PyObject *PyArray_Min (*PyArrayObject* *self, int axis, *PyArrayObject* *out)

Equivalent to `ndarray.min(self, axis)`. Return the smallest element of *self* along the given *axis*. When the result is a single element, returns a numpy scalar instead of an ndarray.

PyObject *PyArray_Ptp (*PyArrayObject* *self, int axis, *PyArrayObject* *out)

Return the difference between the largest element of *self* along *axis* and the smallest element of *self* along *axis*. When the result is a single element, returns a numpy scalar instead of an ndarray.

Note: The rtype argument specifies the data-type the reduction should take place over. This is important if the data-type of the array is not “large” enough to handle the output. By default, all integer data-types are made at least as large

as `NPY_LONG` for the “add” and “multiply” ufuncs (which form the basis for mean, sum, cumsum, prod, and cumprod functions).

PyObject *PyArray_Mean (*PyArrayObject* *self, int axis, int rtype, *PyArrayObject* *out)

Equivalent to `ndarray.mean(self, axis, rtype)`. Returns the mean of the elements along the given *axis*, using the enumerated type *rtype* as the data type to sum in. Default sum behavior is obtained using `NPY_NOTYPE` for *rtype*.

PyObject *PyArray_Trace (*PyArrayObject* *self, int offset, int axis1, int axis2, int rtype, *PyArrayObject* *out)

Equivalent to `ndarray.trace(self, offset, axis1, axis2, rtype)`. Return the sum (using *rtype* as the data type of summation) over the *offset* diagonal elements of the 2-d arrays defined by *axis1* and *axis2* variables. A positive offset chooses diagonals above the main diagonal. A negative offset selects diagonals below the main diagonal.

PyObject *PyArray_Clip (*PyArrayObject* *self, PyObject *min, PyObject *max)

Equivalent to `ndarray.clip(self, min, max)`. Clip an array, *self*, so that values larger than *max* are fixed to *max* and values less than *min* are fixed to *min*.

PyObject *PyArray_Conjugate (*PyArrayObject* *self, *PyArrayObject* *out)

Equivalent to `ndarray.conjugate(self)`. Return the complex conjugate of *self*. If *self* is not of complex data type, then return *self* with a reference.

Parameters

- **self** – Input array.
- **out** – Output array. If provided, the result is placed into this array.

Returns

The complex conjugate of *self*.

PyObject *PyArray_Round (*PyArrayObject* *self, int decimals, *PyArrayObject* *out)

Equivalent to `ndarray.round(self, decimals, out)`. Returns the array with elements rounded to the nearest decimal place. The decimal place is defined as the $10^{-\text{decimals}}$ digit so that negative *decimals* cause rounding to the nearest 10's, 100's, etc. If *out* is NULL, then the output array is created, otherwise the output is placed in *out* which must be the correct size and type.

PyObject *PyArray_Std (*PyArrayObject* *self, int axis, int rtype, *PyArrayObject* *out)

Equivalent to `ndarray.std(self, axis, rtype)`. Return the standard deviation using data along *axis* converted to data type *rtype*.

PyObject *PyArray_Sum (*PyArrayObject* *self, int axis, int rtype, *PyArrayObject* *out)

Equivalent to `ndarray.sum(self, axis, rtype)`. Return 1-d vector sums of elements in *self* along *axis*. Perform the sum after converting data to data type *rtype*.

PyObject *PyArray_CumSum (*PyArrayObject* *self, int axis, int rtype, *PyArrayObject* *out)

Equivalent to `ndarray.cumsum(self, axis, rtype)`. Return cumulative 1-d sums of elements in *self* along *axis*. Perform the sum after converting data to data type *rtype*.

PyObject *PyArray_Prod (*PyArrayObject* *self, int axis, int rtype, *PyArrayObject* *out)

Equivalent to `ndarray.prod(self, axis, rtype)`. Return 1-d products of elements in *self* along *axis*. Perform the product after converting data to data type *rtype*.

PyObject *PyArray_CumProd (*PyArrayObject* *self, int axis, int rtype, *PyArrayObject* *out)

Equivalent to `ndarray.cumprod(self, axis, rtype)`. Return 1-d cumulative products of elements in *self* along *axis*. Perform the product after converting data to data type *rtype*.

`PyObject *PyArray_All (PyArrayObject *self, int axis, PyArrayObject *out)`

Equivalent to `ndarray.all (self, axis)`. Return an array with True elements for every 1-d sub-array of `self` defined by `axis` in which all the elements are True.

`PyObject *PyArray_Any (PyArrayObject *self, int axis, PyArrayObject *out)`

Equivalent to `ndarray.any (self, axis)`. Return an array with True elements for every 1-d sub-array of `self` defined by `axis` in which any of the elements are True.

Functions

Array Functions

`int PyArray_AsCArray (PyObject **op, void *ptr, npy_intp *dims, int nd, PyArray_Descr *typedescr)`

Sometimes it is useful to access a multidimensional array as a C-style multi-dimensional array so that algorithms can be implemented using C's `a[i][j][k]` syntax. This routine returns a pointer, `ptr`, that simulates this kind of C-style array, for 1-, 2-, and 3-d ndarrays.

Parameters

- **op** – The address to any Python object. This Python object will be replaced with an equivalent well-behaved, C-style contiguous, ndarray of the given data type specified by the last two arguments. Be sure that stealing a reference in this way to the input object is justified.
- **ptr** – The address to a (ctype* for 1-d, ctype** for 2-d or ctype*** for 3-d) variable where ctype is the equivalent C-type for the data type. On return, `ptr` will be addressable as a 1-d, 2-d, or 3-d array.
- **dims** – An output array that contains the shape of the array object. This array gives boundaries on any looping that will take place.
- **nd** – The dimensionality of the array (1, 2, or 3).
- **typedescr** – A `PyArray_Descr` structure indicating the desired data-type (including required byteorder). The call will steal a reference to the parameter.

Note: The simulation of a C-style array is not complete for 2-d and 3-d arrays. For example, the simulated arrays of pointers cannot be passed to subroutines expecting specific, statically-defined 2-d and 3-d arrays. To pass to functions requiring those kind of inputs, you must statically define the required array and copy data.

`int PyArray_Free (PyObject *op, void *ptr)`

Must be called with the same objects and memory locations returned from `PyArray_AsCArray (...)`. This function cleans up memory that otherwise would get leaked.

`PyObject *PyArray_Concatenate (PyObject *obj, int axis)`

Join the sequence of objects in `obj` together along `axis` into a single array. If the dimensions or types are not compatible an error is raised.

`PyObject *PyArray_InnerProduct (PyObject *obj1, PyObject *obj2)`

Compute a product-sum over the last dimensions of `obj1` and `obj2`. Neither array is conjugated.

`PyObject *PyArray_MatrixProduct (PyObject *obj1, PyObject *obj2)`

Compute a product-sum over the last dimension of `obj1` and the second-to-last dimension of `obj2`. For 2-d arrays this is a matrix-product. Neither array is conjugated.

PyObject *PyArray_MatrixProduct2 (PyObject *obj1, PyObject *obj, *PyArrayObject* *out)

Same as `PyArray_MatrixProduct`, but store the result in *out*. The output array must have the correct shape, type, and be C-contiguous, or an exception is raised.

PyArrayObject *PyArray_EinsteinSum (char *subscripts, *numpy_intp* nop, *PyArrayObject* **op_in, *PyArray_Descr* *dtype, *NPY_ORDER* order, *NPY_CASTING* casting, *PyArrayObject* *out)

Applies the Einstein summation convention to the array operands provided, returning a new array or placing the result in *out*. The string in *subscripts* is a comma separated list of index letters. The number of operands is in *nop*, and *op_in* is an array containing those operands. The data type of the output can be forced with *dtype*, the output order can be forced with *order* (*NPY_KEEPOORDER* is recommended), and when *dtype* is specified, *casting* indicates how permissive the data conversion should be.

See the `einsum` function for more details.

PyObject *PyArray_Correlate (PyObject *op1, PyObject *op2, int mode)

Compute the 1-d correlation of the 1-d arrays *op1* and *op2*. The correlation is computed at each output point by multiplying *op1* by a shifted version of *op2* and summing the result. As a result of the shift, needed values outside of the defined range of *op1* and *op2* are interpreted as zero. The mode determines how many shifts to return: 0 - return only shifts that did not need to assume zero- values; 1 - return an object that is the same size as *op1*, 2 - return all possible shifts (any overlap at all is accepted).

Notes

This does not compute the usual correlation: if *op2* is larger than *op1*, the arguments are swapped, and the conjugate is never taken for complex arrays. See `PyArray_Correlate2` for the usual signal processing correlation.

PyObject *PyArray_Correlate2 (PyObject *op1, PyObject *op2, int mode)

Updated version of `PyArray_Correlate`, which uses the usual definition of correlation for 1d arrays. The correlation is computed at each output point by multiplying *op1* by a shifted version of *op2* and summing the result. As a result of the shift, needed values outside of the defined range of *op1* and *op2* are interpreted as zero. The mode determines how many shifts to return: 0 - return only shifts that did not need to assume zero- values; 1 - return an object that is the same size as *op1*, 2 - return all possible shifts (any overlap at all is accepted).

Notes

Compute *z* as follows:

$$z[k] = \sum_n op1[n] * conj(op2[n+k])$$

PyObject *PyArray_Where (PyObject *condition, PyObject *x, PyObject *y)

If both *x* and *y* are NULL, then return `PyArray_Nonzero(condition)`. Otherwise, both *x* and *y* must be given and the object returned is shaped like *condition* and has elements of *x* and *y* where *condition* is respectively True or False.

Other functions

numpy_bool **PyArray_CheckStrides** (int elsize, int nd, *numpy_intp* numbytes, *numpy_intp* const *dims, *numpy_intp* const *newstrides)

Determine if *newstrides* is a strides array consistent with the memory of an *nd* -dimensional array with shape *dims* and element-size, *elsize*. The *newstrides* array is checked to see if jumping by the provided number of bytes in each direction will ever mean jumping more than *numbytes* which is the assumed size of the available memory segment. If *numbytes* is 0, then an equivalent *numbytes* is computed assuming *nd*, *dims*, and *elsize* refer to a single-segment array. Return *NPY_TRUE* if *newstrides* is acceptable, otherwise return *NPY_FALSE*.

numpy_intp **PyArray_MultiplyList** (*numpy_intp* const *seq, int n)

int **PyArray_MultiplyIntList** (int const *seq, int n)

Both of these routines multiply an *n* -length array, *seq*, of integers and return the result. No overflow checking is performed.

int **PyArray_CompareLists** (*numpy_intp* const *l1, *numpy_intp* const *l2, int n)

Given two *n* -length arrays of integers, *l1*, and *l2*, return 1 if the lists are identical; otherwise, return 0.

Auxiliary data with object semantics

type **NpyAuxData**

When working with more complex dtypes which are composed of other dtypes, such as the struct dtype, creating inner loops that manipulate the dtypes requires carrying along additional data. NumPy supports this idea through a struct *NpyAuxData*, mandating a few conventions so that it is possible to do this.

Defining an *NpyAuxData* is similar to defining a class in C++, but the object semantics have to be tracked manually since the API is in C. Here's an example for a function which doubles up an element using an element copier function as a primitive.

```
typedef struct {
    NpyAuxData base;
    ElementCopier_Func *func;
    NpyAuxData *funcdata;
} eldoubler_aux_data;

void free_element_doubler_aux_data(NpyAuxData *data)
{
    eldoubler_aux_data *d = (eldoubler_aux_data *)data;
    /* Free the memory owned by this auxdata */
    NPY_AUXDATA_FREE(d->funcdata);
    PyArray_free(d);
}

NpyAuxData *clone_element_doubler_aux_data(NpyAuxData *data)
{
    eldoubler_aux_data *ret = PyArray_malloc(sizeof(eldoubler_aux_data));
    if (ret == NULL) {
        return NULL;
    }

    /* Raw copy of all data */
    memcpy(ret, data, sizeof(eldoubler_aux_data));

    /* Fix up the owned auxdata so we have our own copy */
```

(continues on next page)

(continued from previous page)

```

    ret->funcdata = NPY_AUXDATA_CLONE (ret->funcdata);
    if (ret->funcdata == NULL) {
        PyArray_free (ret);
        return NULL;
    }

    return (NpyAuxData *)ret;
}

NpyAuxData *create_element_doubler_aux_data (
    ElementCopier_Func *func,
    NpyAuxData *funcdata)
{
    eldoubler_aux_data *ret = PyArray_malloc (sizeof (eldoubler_aux_data));
    if (ret == NULL) {
        PyErr_NoMemory ();
        return NULL;
    }
    memset (&ret, 0, sizeof (eldoubler_aux_data));
    ret->base->free = &free_element_doubler_aux_data;
    ret->base->clone = &clone_element_doubler_aux_data;
    ret->func = func;
    ret->funcdata = funcdata;

    return (NpyAuxData *)ret;
}

```

type `NpyAuxData_FreeFunc`

The function pointer type for NpyAuxData free functions.

type `NpyAuxData_CloneFunc`

The function pointer type for NpyAuxData clone functions. These functions should never set the Python exception on error, because they may be called from a multi-threaded context.

void **NPY_AUXDATA_FREE** (*NpyAuxData* *auxdata)

A macro which calls the auxdata's free function appropriately, does nothing if auxdata is NULL.

NpyAuxData ***NPY_AUXDATA_CLONE** (*NpyAuxData* *auxdata)

A macro which calls the auxdata's clone function appropriately, returning a deep copy of the auxiliary data.

Array iterators

As of NumPy 1.6.0, these array iterators are superseded by the new array iterator, *NpyIter*.

An array iterator is a simple way to access the elements of an N-dimensional array quickly and efficiently, as seen in *the example* which provides more description of this useful approach to looping over an array from C.

PyObject ***PyArray_IterNew** (*PyObject* *arr)

Return an array iterator object from the array, *arr*. This is equivalent to *arr.flat*. The array iterator object makes it easy to loop over an N-dimensional non-contiguous array in C-style contiguous fashion.

PyObject ***PyArray_IterAllButAxis** (*PyObject* *arr, int *axis)

Return an array iterator that will iterate over all axes but the one provided in **axis*. The returned iterator cannot be used with *PyArray_ITER_GOTO1D*. This iterator could be used to write something similar to what *ufuncs* do wherein the loop over the largest axis is done by a separate sub-routine. If **axis* is negative then **axis* will be set to the axis having the smallest stride and that axis will be used.

`PyObject *PyArray_BroadcastToShape (PyObject *arr, numpy_intp const *dimensions, int nd)`

Return an array iterator that is broadcast to iterate as an array of the shape provided by *dimensions* and *nd*.

`int PyArrayIter_Check (PyObject *op)`

Evaluates true if *op* is an array iterator (or instance of a subclass of the array iterator type).

`void PyArray_ITER_RESET (PyObject *iterator)`

Reset an *iterator* to the beginning of the array.

`void PyArray_ITER_NEXT (PyObject *iterator)`

Increment the index and the dataptr members of the *iterator* to point to the next element of the array. If the array is not (C-style) contiguous, also increment the N-dimensional coordinates array.

`void *PyArray_ITER_DATA (PyObject *iterator)`

A pointer to the current element of the array.

`void PyArray_ITER_GOTO (PyObject *iterator, numpy_intp *destination)`

Set the *iterator* index, dataptr, and coordinates members to the location in the array indicated by the N-dimensional c-array, *destination*, which must have size at least *iterator* ->nd_m1+1.

`void PyArray_ITER_GOTO1D (PyObject *iterator, numpy_intp index)`

Set the *iterator* index and dataptr to the location in the array indicated by the integer *index* which points to an element in the C-styled flattened array.

`int PyArray_ITER_NOTDONE (PyObject *iterator)`

Evaluates TRUE as long as the iterator has not looped through all of the elements, otherwise it evaluates FALSE.

Broadcasting (multi-iterators)

`PyObject *PyArray_MultiIterNew (int num, ...)`

A simplified interface to broadcasting. This function takes the number of arrays to broadcast and then *num* extra (`PyObject *`) arguments. These arguments are converted to arrays and iterators are created. `PyArray_Broadcast` is then called on the resulting multi-iterator object. The resulting, broadcasted multi-iterator object is then returned. A broadcasted operation can then be performed using a single loop and using `PyArray_MultiIter_NEXT(..)`

`void PyArray_MultiIter_RESET (PyObject *multi)`

Reset all the iterators to the beginning in a multi-iterator object, *multi*.

`void PyArray_MultiIter_NEXT (PyObject *multi)`

Advance each iterator in a multi-iterator object, *multi*, to its next (broadcasted) element.

`void *PyArray_MultiIter_DATA (PyObject *multi, int i)`

Return the data-pointer of the *i*th iterator in a multi-iterator object.

`void PyArray_MultiIter_NEXTi (PyObject *multi, int i)`

Advance the pointer of only the *i*th iterator.

`void PyArray_MultiIter_GOTO (PyObject *multi, numpy_intp *destination)`

Advance each iterator in a multi-iterator object, *multi*, to the given *N* -dimensional *destination* where *N* is the number of dimensions in the broadcasted array.

`void PyArray_MultiIter_GOTO1D (PyObject *multi, numpy_intp index)`

Advance each iterator in a multi-iterator object, *multi*, to the corresponding location of the *index* into the flattened broadcasted array.

int **PyArray_MultiIter_NOTDONE** (*PyObject* *multi)

Evaluates TRUE as long as the multi-iterator has not looped through all of the elements (of the broadcasted result), otherwise it evaluates FALSE.

numpy_intp **PyArray_MultiIter_SIZE** (*PyArrayMultiIterObject* *multi)

New in version 1.26.0.

Returns the total broadcasted size of a multi-iterator object.

int **PyArray_MultiIter_NDIM** (*PyArrayMultiIterObject* *multi)

New in version 1.26.0.

Returns the number of dimensions in the broadcasted result of a multi-iterator object.

numpy_intp **PyArray_MultiIter_INDEX** (*PyArrayMultiIterObject* *multi)

New in version 1.26.0.

Returns the current (1-d) index into the broadcasted result of a multi-iterator object.

int **PyArray_MultiIter_NUMITER** (*PyArrayMultiIterObject* *multi)

New in version 1.26.0.

Returns the number of iterators that are represented by a multi-iterator object.

void ****PyArray_MultiIter_ITERS** (*PyArrayMultiIterObject* *multi)

New in version 1.26.0.

Returns an array of iterator objects that holds the iterators for the arrays to be broadcast together. On return, the iterators are adjusted for broadcasting.

numpy_intp ***PyArray_MultiIter_DIMS** (*PyArrayMultiIterObject* *multi)

New in version 1.26.0.

Returns a pointer to the dimensions/shape of the broadcasted result of a multi-iterator object.

int **PyArray_Broadcast** (*PyArrayMultiIterObject* *mit)

This function encapsulates the broadcasting rules. The *mit* container should already contain iterators for all the arrays that need to be broadcast. On return, these iterators will be adjusted so that iteration over each simultaneously will accomplish the broadcasting. A negative number is returned if an error occurs.

int **PyArray_RemoveSmallest** (*PyArrayMultiIterObject* *mit)

This function takes a multi-iterator object that has been previously “broadcasted,” finds the dimension with the smallest “sum of strides” in the broadcasted result and adapts all the iterators so as not to iterate over that dimension (by effectively making them of length-1 in that dimension). The corresponding dimension is returned unless *mit* ->nd is 0, then -1 is returned. This function is useful for constructing ufunc-like routines that broadcast their inputs correctly and then call a strided 1-d version of the routine as the inner-loop. This 1-d version is usually optimized for speed and for this reason the loop should be performed over the axis that won’t require large stride jumps.

Neighborhood iterator

Neighborhood iterators are subclasses of the iterator object, and can be used to iter over a neighborhood of a point. For example, you may want to iterate over every voxel of a 3d image, and for every such voxel, iterate over an hypercube. Neighborhood iterator automatically handle boundaries, thus making this kind of code much easier to write than manual boundaries handling, at the cost of a slight overhead.

PyObject ***PyArray_NeighborhoodIterNew** (*PyArrayIterObject* *iter, *numpy_intp* bounds, int mode, *PyArrayObject* *fill_value)

This function creates a new neighborhood iterator from an existing iterator. The neighborhood will be computed relatively to the position currently pointed by *iter*, the bounds define the shape of the neighborhood iterator, and the mode argument the boundaries handling mode.

The *bounds* argument is expected to be a (2 * iter->ao->nd) arrays, such as the range bound[2*i]->bounds[2*i+1] defines the range where to walk for dimension i (both bounds are included in the walked coordinates). The bounds should be ordered for each dimension (bounds[2*i] <= bounds[2*i+1]).

The mode should be one of:

NPY_NEIGHBORHOOD_ITER_ZERO_PADDING

Zero padding. Outside bounds values will be 0.

NPY_NEIGHBORHOOD_ITER_ONE_PADDING

One padding. Outside bounds values will be 1.

NPY_NEIGHBORHOOD_ITER_CONSTANT_PADDING

Constant padding. Outside bounds values will be the same as the first item in fill_value.

NPY_NEIGHBORHOOD_ITER_MIRROR_PADDING

Mirror padding. Outside bounds values will be as if the array items were mirrored. For example, for the array [1, 2, 3, 4], x[-2] will be 2, x[-2] will be 1, x[4] will be 4, x[5] will be 1, etc...

NPY_NEIGHBORHOOD_ITER_CIRCULAR_PADDING

Circular padding. Outside bounds values will be as if the array was repeated. For example, for the array [1, 2, 3, 4], x[-2] will be 3, x[-2] will be 4, x[4] will be 1, x[5] will be 2, etc...

If the mode is constant filling (*NPY_NEIGHBORHOOD_ITER_CONSTANT_PADDING*), fill_value should point to an array object which holds the filling value (the first item will be the filling value if the array contains more than one item). For other cases, fill_value may be NULL.

- The iterator holds a reference to iter
- Return NULL on failure (in which case the reference count of iter is not changed)
- iter itself can be a Neighborhood iterator: this can be useful for .e.g automatic boundaries handling
- the object returned by this function should be safe to use as a normal iterator
- If the position of iter is changed, any subsequent call to PyArrayNeighborhoodIter_Next is undefined behavior, and PyArrayNeighborhoodIter_Reset must be called.
- If the position of iter is not the beginning of the data and the underlying data for iter is contiguous, the iterator will point to the start of the data instead of position pointed by iter. To avoid this situation, iter should be moved to the required position only after the creation of iterator, and PyArrayNeighborhoodIter_Reset must be called.

```
PyArrayIterObject *iter;
PyArrayNeighborhoodIterObject *neigh_iter;
iter = PyArray_IterNew(x);

/*For a 3x3 kernel */
bounds = {-1, 1, -1, 1};
neigh_iter = (PyArrayNeighborhoodIterObject*)PyArray_NeighborhoodIterNew(
    iter, bounds, NPY_NEIGHBORHOOD_ITER_ZERO_PADDING, NULL);

for(i = 0; i < iter->size; ++i) {
    for (j = 0; j < neigh_iter->size; ++j) {
        /* Walk around the item currently pointed by iter->dataptr */
```

(continues on next page)

(continued from previous page)

```

        PyArrayNeighborhoodIter_Next(neigh_iter);
    }

    /* Move to the next point of iter */
    PyArrayIter_Next(iter);
    PyArrayNeighborhoodIter_Reset(neigh_iter);
}

```

int **PyArrayNeighborhoodIter_Reset** (*PyArrayNeighborhoodIterObject* *iter)

Reset the iterator position to the first point of the neighborhood. This should be called whenever the iter argument given at `PyArray_NeighborhoodIterObject` is changed (see example)

int **PyArrayNeighborhoodIter_Next** (*PyArrayNeighborhoodIterObject* *iter)

After this call, `iter->dataptr` points to the next point of the neighborhood. Calling this function after every point of the neighborhood has been visited is undefined.

Array scalars

PyObject ***PyArray_Return** (*PyArrayObject* *arr)

This function steals a reference to *arr*.

This function checks to see if *arr* is a 0-dimensional array and, if so, returns the appropriate array scalar. It should be used whenever 0-dimensional arrays could be returned to Python.

PyObject ***PyArray_Scalar** (void *data, *PyArray_Descr* *dtype, *PyObject* *base)

Return an array scalar object of the given *dtype* by **copying** from memory pointed to by *data*. *base* is expected to be the array object that is the owner of the data. *base* is required if *dtype* is a void scalar, or if the `NPY_USE_GETITEM` flag is set and it is known that the `getitem` method uses the *arr* argument without checking if it is NULL. Otherwise *base* may be NULL.

If the data is not in native byte order (as indicated by `dtype->byteorder`) then this function will byteswap the data, because array scalars are always in correct machine-byte order.

PyObject ***PyArray_ToScalar** (void *data, *PyArrayObject* *arr)

Return an array scalar object of the type and itemsize indicated by the array object *arr* copied from the memory pointed to by *data* and swapping if the data in *arr* is not in machine byte-order.

PyObject ***PyArray_FromScalar** (*PyObject* *scalar, *PyArray_Descr* *outcode)

Return a 0-dimensional array of type determined by *outcode* from *scalar* which should be an array-scalar object. If *outcode* is NULL, then the type is determined from *scalar*.

void **PyArray_ScalarAsCtype** (*PyObject* *scalar, void *ctypeptr)

Return in *ctypeptr* a pointer to the actual value in an array scalar. There is no error checking so *scalar* must be an array-scalar object, and *ctypeptr* must have enough space to hold the correct type. For flexible-sized types, a pointer to the data is copied into the memory of *ctypeptr*, for all other types, the actual data is copied into the address pointed to by *ctypeptr*.

int **PyArray_CastScalarToCtype** (*PyObject* *scalar, void *ctypeptr, *PyArray_Descr* *outcode)

Return the data (cast to the data type indicated by *outcode*) from the array-scalar, *scalar*, into the memory pointed to by *ctypeptr* (which must be large enough to handle the incoming memory).

Returns -1 on failure, and 0 on success.

`PyObject *PyArray_TypeObjectFromType` (int type)

Returns a scalar type-object from a type-number, *type* . Equivalent to `PyArray_DescrFromType` (*type*)->typeobj except for reference counting and error-checking. Returns a new reference to the typeobject on success or NULL on failure.

`NPY_SCALARKIND PyArray_ScalarKind` (int typenum, `PyArrayObject` **arr)

Legacy way to query special promotion for scalar values. This is not used in NumPy itself anymore and is expected to be deprecated eventually.

New DTypes can define promotion rules specific to Python scalars.

int `PyArray_CanCoerceScalar` (char thistype, char neededtype, `NPY_SCALARKIND` scalar)

Legacy way to query special promotion for scalar values. This is not used in NumPy itself anymore and is expected to be deprecated eventually.

Use `PyArray_ResultType` for similar purposes.

Data-type descriptors

Warning: Data-type objects must be reference counted so be aware of the action on the data-type reference of different C-API calls. The standard rule is that when a data-type object is returned it is a new reference. Functions that take `PyArray_Descr*` objects and return arrays steal references to the data-type their inputs unless otherwise noted. Therefore, you must own a reference to any data-type object used as input to such a function.

int `PyArray_DescrCheck` (`PyObject` *obj)

Evaluates as true if *obj* is a data-type object (`PyArray_Descr*`).

`PyArray_Descr` *`PyArray_DescrNew` (`PyArray_Descr` *obj)

Return a new data-type object copied from *obj* (the fields reference is just updated so that the new object points to the same fields dictionary if any).

`PyArray_Descr` *`PyArray_DescrNewFromType` (int typenum)

Create a new data-type object from the built-in (or user-registered) data-type indicated by *typenum*. All builtin types should not have any of their fields changed. This creates a new copy of the `PyArray_Descr` structure so that you can fill it in as appropriate. This function is especially needed for flexible data-types which need to have a new `elsize` member in order to be meaningful in array construction.

`PyArray_Descr` *`PyArray_DescrNewByteorder` (`PyArray_Descr` *obj, char newendian)

Create a new data-type object with the byteorder set according to *newendian*. All referenced data-type objects (in `subdescr` and `fields` members of the data-type object) are also changed (recursively).

The value of *newendian* is one of these macros:

`NPY_IGNORE`

`NPY_SWAP`

`NPY_NATIVE`

`NPY_LITTLE`

`NPY_BIG`

If a byteorder of `NPY_IGNORE` is encountered it is left alone. If *newendian* is `NPY_SWAP`, then all byte-orders are swapped. Other valid *newendian* values are `NPY_NATIVE`, `NPY_LITTLE`, and `NPY_BIG` which all cause the returned data-typed descriptor (and all it's referenced data-type descriptors) to have the corresponding byte-order.

PyArray_Descr ***PyArray_DescrFromObject** (PyObject *op, *PyArray_Descr* *mintype)

Determine an appropriate data-type object from the object *op* (which should be a “nested” sequence object) and the minimum data-type descriptor mintype (which can be NULL). Similar in behavior to `array(op).dtype`. Don’t confuse this function with *PyArray_DescrConverter*. This function essentially looks at all the objects in the (nested) sequence and determines the data-type from the elements it finds.

PyArray_Descr ***PyArray_DescrFromScalar** (PyObject *scalar)

Return a data-type object from an array-scalar object. No checking is done to be sure that *scalar* is an array scalar. If no suitable data-type can be determined, then a data-type of `NPY_OBJECT` is returned by default.

PyArray_Descr ***PyArray_DescrFromType** (int typenum)

Returns a data-type object corresponding to *typenum*. The *typenum* can be one of the enumerated types, a character code for one of the enumerated types, or a user-defined type. If you want to use a flexible size array, then you need to flexible *typenum* and set the results *elsize* parameter to the desired size. The *typenum* is one of the `NPY_TYPES`.

int **PyArray_DescrConverter** (PyObject *obj, *PyArray_Descr* **dtype)

Convert any compatible Python object, *obj*, to a data-type object in *dtype*. A large number of Python objects can be converted to data-type objects. See *Data type objects (dtype)* for a complete description. This version of the converter converts None objects to a `NPY_DEFAULT_TYPE` data-type object. This function can be used with the “O&” character code in *PyArg_ParseTuple* processing.

int **PyArray_DescrConverter2** (PyObject *obj, *PyArray_Descr* **dtype)

Convert any compatible Python object, *obj*, to a data-type object in *dtype*. This version of the converter converts None objects so that the returned data-type is NULL. This function can also be used with the “O&” character in *PyArg_ParseTuple* processing.

int **PyArray_DescrAlignConverter** (PyObject *obj, *PyArray_Descr* **dtype)

Like *PyArray_DescrConverter* except it aligns C-struct-like objects on word-boundaries as the compiler would.

int **PyArray_DescrAlignConverter2** (PyObject *obj, *PyArray_Descr* **dtype)

Like *PyArray_DescrConverter2* except it aligns C-struct-like objects on word-boundaries as the compiler would.

Data Type Promotion and Inspection

PyArray_DTypeMeta ***PyArray_CommonDType** (const *PyArray_DTypeMeta* *dtype1, const *PyArray_DTypeMeta* *dtype2)

This function defines the common DType operator. Note that the common DType will not be object (unless one of the DTypes is object). Similar to `numpy.result_type`, but works on the classes and not instances.

PyArray_DTypeMeta ***PyArray_PromoteDTypeSequence** (*numpy_intp* length, *PyArray_DTypeMeta* **dtypes_in)

Promotes a list of DTypes with each other in a way that should guarantee stable results even when changing the order. This function is smarter and can often return successful and unambiguous results when `common_dtype(common_dtype(dt1, dt2), dt3)` would depend on the operation order or fail. Nevertheless, DTypes should aim to ensure that their common-dtype implementation is associative and commutative! (Mainly, unsigned and signed integers are not.)

For guaranteed consistent results DTypes must implement common-Dtype “transitively”. If A promotes B and B promotes C, then A must generally also promote C; where “promotes” means implements the promotion. (There are some exceptions for abstract DTypes)

In general this approach always works as long as the most generic dtype is either strictly larger, or compatible with all other dtypes. For example promoting `float16` with any other float, integer, or unsigned integer again gives a floating point number.

PyArray_Descr ***PyArray_GetDefaultDescr** (const *PyArray_DTypeMeta* *DType)

Given a DType class, returns the default instance (descriptor). This checks for a singleton first and only calls the `default_descr` function if necessary.

Custom Data Types

New in version 2.0.

These functions allow defining custom flexible data types outside of NumPy. See [NEP 42](#) for more details about the rationale and design of the new DType system. See the [numpy-user-dtypes repository](#) for a number of example DTypes. Also see *PyArray_DTypeMeta* and *PyArrayDTypeMeta_Spec* for documentation on *PyArray_DTypeMeta* and *PyArrayDTypeMeta_Spec*.

int **PyArrayInitDTypeMeta_FromSpec** (*PyArray_DTypeMeta* *Dtype, *PyArrayDTypeMeta_Spec* *spec)

Initialize a new DType. It must currently be a static Python C type that is declared as *PyArray_DTypeMeta* and not *PyTypeObject*. Further, it must subclass *np.dtype* and set its type to *PyArrayDTypeMeta_Type* (before calling *PyType_Ready*), which has additional fields compared to a normal *PyTypeObject*. See the examples in the [numpy-user-dtypes repository](#) for usage with both parametric and non-parametric data types.

Note: Custom DType registration is expected to happen during module import. The registration API mutates global state and is not thread-safe.

Flags

Flags that can be set on the *PyArrayDTypeMeta_Spec* to initialize the DType.

NPY_DT_ABSTRACT

Indicates the DType is an abstract “base” DType in a DType hierarchy and should not be directly instantiated.

NPY_DT_PARAMETRIC

Indicates the DType is parametric and does not have a unique singleton instance.

NPY_DT_NUMERIC

Indicates the DType represents a numerical value.

Slot IDs and API Function Typedefs

These IDs correspond to slots in the DType API and are used to identify implementations of each slot from the items of the `slots` array member of *PyArrayDTypeMeta_Spec* struct.

NPY_DT_legacy_descriptor_proto

Compatibility slot to transition legacy dtypes to the new DType API. Existing legacy dtypes that currently use *PyArray_RegisterDataType* should use this to transition to the new DType API. The value of this slot is the *PyArray_DescrProto* struct.

This slot allows an *existing* legacy DType to use the new DType API without breaking backwards compatibility (or with very minor changes). I.e. NumPy will still consider this a “legacy” DType and use old code paths where applicable, but use new features as they become available.

If used, this slot is required to be the first slot. The `ArrFuncs` fields are copied, but you may also set them via the slots below. (This allows backporting e.g. `sorts`, although NumPy 2.4+ does support a new way to implement `sorts`.)

New in version 2.5: This feature is added in NumPy 2.5, but is backported to be compatible with NumPy 2.0+. You can vendor this backport from `numpy_2_compat.h` if you wish to compile with older NumPy versions.

Note: This slot exists for DTypes that currently use `PyArray_RegisterDataType` allowing them to transition when otherwise regressions would block them from doing so. It is a path for deprecating `PyArray_RegisterDataType`, `PyArray_RegisterCastFunc`, `PyArray_RegisterCanCast` and further slots in the future.

NPY_DT_discover_descr_from_pyobject

```
typedef PyArray_Descr (PyArrayDTypeMeta_DiscoverDescrFromPyObject)(PyArray_DTypeMeta *cls,
PyObject *obj)
```

Used during DType inference to find the correct DType for a given PyObject. Must return a descriptor instance appropriate to store the data in the python object that is passed in. *obj* is the python object to inspect and *cls* is the DType class to create a descriptor for.

NPY_DT_default_descr

```
typedef PyArray_Descr (PyArrayDTypeMeta_DefaultDescriptor)(PyArray_DTypeMeta *cls)
```

Returns the default descriptor instance for the DType. Must be defined for parametric data types. Non-parametric data types return the singleton by default.

NPY_DT_common_dtype

```
typedef PyArray_DTypeMeta (PyArrayDTypeMeta_CommonDType)(PyArray_DTypeMeta *dtype1,
PyArray_DTypeMeta *dtype2)
```

Given two input DTypes, determines the appropriate “common” DType that can store values for both types. Returns `Py_NotImplemented` if no such type exists.

NPY_DT_common_instance

```
typedef PyArray_Descr (PyArrayDTypeMeta_CommonInstance)(PyArray_Descr *dtype1, PyArray_Descr
*dtype2)
```

Given two input descriptors, determines the appropriate “common” descriptor that can store values for both instances. Returns `NULL` on error.

NPY_DT_ensure_canonical

```
typedef PyArray_Descr (PyArrayDTypeMeta_EnsureCanonical)(PyArray_Descr *dtype)
```

Returns the “canonical” representation for a descriptor instance. The notion of a canonical descriptor generalizes the concept of byte order, in that a canonical descriptor always has native byte order. If the descriptor is already canonical, this function returns a new reference to the input descriptor.

NPY_DT_setitem

```
typedef int (PyArrayDTypeMeta_SetItem)(PyArray_Descr*, PyObject*, char*)
```

Implements scalar setitem for an array element given a PyObject.

NPY_DT_getitem

```
typedef PyObject (PyArrayDTypeMeta_GetItem)(PyArray_Descr*, char*)
```

Implements scalar getitem for an array element. Must return a python scalar.

NPY_DT_get_clear_loop

If defined, sets a traversal loop that clears data in the array. This is most useful for arrays of references that must clean up array entries before the array is garbage collected. Implements `PyArrayMethod_GetTraverseLoop`.

NPY_DT_get_fill_zero_loop

If defined, sets a traversal loop that fills an array with “zero” values, which may have a DType-specific meaning. This is called inside `numpy.zeros` for arrays that need to write a custom sentinel value that represents zero if for some reason a zero-filled array is not sufficient. Implements `PyArrayMethod_GetTraverseLoop`.

NPY_DT_finalize_descr

typedef *PyArray_Descr* **(PyArrayDTypeMeta_FinalizeDescriptor)**(*PyArray_Descr* *dtype)

If defined, a function that is called to “finalize” a descriptor instance after an array is created. One use of this function is to force newly created arrays to have a newly created descriptor instance, no matter what input descriptor is provided by a user.

NPY_DT_get_constant

typedef int **(PyArrayDTypeMeta_GetConstant)**(*PyArray_Descr* *descr, int constant_id, void *out)

If defined, allows the DType to expose constant values such as machine limits, special values (infinity, NaN), and floating-point characteristics. The *descr* is the descriptor instance, *constant_id* is one of the `NPY_CONSTANT_*` macros, and *out* is a pointer to uninitialized memory where the constant value should be written. The memory pointed to by *out* may be unaligned and is uninitialized. Returns 1 on success, 0 if the constant is not available, or -1 with an error set.

Constant IDs:

The following constant IDs are defined for retrieving dtype-specific values:

Basic constants (available for all numeric types):

NPY_CONSTANT_zero

The zero value for the dtype.

NPY_CONSTANT_one

The one value for the dtype.

NPY_CONSTANT_minimum_finite

The minimum finite value representable by the dtype. For floating-point types, this is the most negative finite value (e.g., `-FLT_MAX`).

NPY_CONSTANT_maximum_finite

The maximum finite value representable by the dtype.

Floating-point special values:**NPY_CONSTANT_inf**

Positive infinity (only for floating-point types).

NPY_CONSTANT_ninf

Negative infinity (only for floating-point types).

NPY_CONSTANT_nan

Not-a-Number (only for floating-point types).

Floating-point characteristics (values of the dtype’s native type):**NPY_CONSTANT_finfo_radix**

The radix (base) of the floating-point representation. This is 2 for all floating-point types.

NPY_CONSTANT_finfo_eps

Machine epsilon: the difference between 1.0 and the next representable value greater than 1.0. Corresponds to C macros like `FLT_EPSILON`, `DBL_EPSILON`.

Note: For long double in IBM double-double format (PowerPC), this is defined as $0 \times 1p-105L$ (2^{-105}) based on the ~106 bits of mantissa precision.

NPY_CONSTANT_finfo_epsneg

The difference between 1.0 and the next representable value less than 1.0. Typically `eps / radix` for binary floating-point types.

NPY_CONSTANT_finfo_smallest_normal

The smallest positive normalized floating-point number. Corresponds to C macros like `FLT_MIN`, `DBL_MIN`. This is the smallest value with a leading 1 bit in the mantissa.

NPY_CONSTANT_finfo_smallest_subnormal

The smallest positive subnormal (denormalized) floating-point number. Corresponds to C macros like `FLT_TRUE_MIN`, `DBL_TRUE_MIN`. This is the smallest representable positive value, with leading 0 bits in the mantissa.

Floating-point characteristics (integer values, type `numpy_intp`):

These constants return integer metadata about the floating-point representation. They are marked with the 1 << 16 bit to indicate they return `numpy_intp` values rather than the dtype's native type.

NPY_CONSTANT_finfo_nmant

Number of mantissa bits (excluding the implicit leading bit). For example, IEEE 754 binary64 (double) has 52 explicit mantissa bits, so this returns 52. Corresponds to `MANT_DIG - 1` from C standard macros.

NPY_CONSTANT_finfo_min_exp

Minimum exponent value. This is the minimum negative integer such that the radix raised to the power of one less than that integer is a normalized floating-point number. Corresponds to `MIN_EXP - 1` from C standard macros (e.g., `FLT_MIN_EXP - 1`).

NPY_CONSTANT_finfo_max_exp

Maximum exponent value. This is the maximum positive integer such that the radix raised to the power of one less than that integer is a representable finite floating-point number. Corresponds to `MAX_EXP` from C standard macros (e.g., `FLT_MAX_EXP`).

NPY_CONSTANT_finfo_decimal_digits

The number of decimal digits of precision. Corresponds to `DIG` from C standard macros (e.g., `FLT_DIG`, `DBL_DIG`).

PyArray_ArrFuncs slots

In addition the above slots, the following slots are exposed to allow filling the *PyArray_ArrFuncs* struct attached to descriptor instances. Note that in the future these will be replaced by proper DType API slots but for now we have exposed the legacy *PyArray_ArrFuncs* slots.

NPY_DT_PyArray_ArrFuncs_getitem

Allows setting a per-dtype `getitem`. Note that this is not necessary to define unless the default version calling the function defined with the `NPY_DT_getitem` ID is unsuitable. This version will be slightly faster than using `NPY_DT_getitem` at the cost of sometimes needing to deal with a NULL input array.

NPY_DT_PyArray_ArrFuncs_setitem

Allows setting a per-dtype setitem. Note that this is not necessary to define unless the default version calling the function defined with the `NPY_DT_setitem` ID is unsuitable for some reason.

NPY_DT_PyArray_ArrFuncs_compare

Computes a comparison for `numpy.sort`, implements `PyArray_CompareFunc`.

NPY_DT_PyArray_ArrFuncs_argmax

Computes the argmax for `numpy.argmax`, implements `PyArray_ArgFunc`.

NPY_DT_PyArray_ArrFuncs_argmin

Computes the argmin for `numpy.argmin`, implements `PyArray_ArgFunc`.

NPY_DT_PyArray_ArrFuncs_dotfunc

Computes the dot product for `numpy.dot`, implements `PyArray_DotFunc`.

NPY_DT_PyArray_ArrFuncs_scanfunc

A formatted input function for `numpy.fromfile`, implements `PyArray_ScanFunc`.

NPY_DT_PyArray_ArrFuncs_fromstr

A string parsing function for `numpy.fromstring`, implements `PyArray_FromStrFunc`.

NPY_DT_PyArray_ArrFuncs_nonzero

Computes the nonzero function for `numpy.nonzero`, implements `PyArray_NonzeroFunc`.

NPY_DT_PyArray_ArrFuncs_fill

An array filling function for `numpy.ndarray.fill`, implements `PyArray_FillFunc`.

NPY_DT_PyArray_ArrFuncs_fillwithscalar

A function to fill an array with a scalar value for `numpy.ndarray.fill`, implements `PyArray_FillWithScalarFunc`.

NPY_DT_PyArray_ArrFuncs_sort

An array of `PyArray_SortFunc` of length `NPY_NSORTS`. If set, allows defining custom sorting implementations for each of the sorting algorithms numpy implements.

NPY_DT_PyArray_ArrFuncs_argsort

An array of `PyArray_ArgSortFunc` of length `NPY_NSORTS`. If set, allows defining custom argsorting implementations for each of the sorting algorithms numpy implements.

Macros and Static Inline Functions

These macros and static inline functions are provided to allow more understandable and idiomatic code when working with `PyArray_DTypeMeta` instances.

NPY_DTYPE (descr)

Returns a `PyArray_DTypeMeta *` pointer to the `DType` of a given descriptor instance.

static inline `PyArray_DTypeMeta *NPY_DT_NewRef(PyArray_DTypeMeta *o)`

Returns a `PyArray_DTypeMeta *` pointer to a new reference to a `DType`.

Conversion utilities

For use with `PyArg_ParseTuple`

All of these functions can be used in `PyArg_ParseTuple(...)` with the “O&” format specifier to automatically convert any Python object to the required C-object. All of these functions return `NPY_SUCCEED` if successful and `NPY_FAIL` if not. The first argument to all of these function is a Python object. The second argument is the **address** of the C-type to convert the Python object to.

Warning: Be sure to understand what steps you should take to manage the memory when using these conversion functions. These functions can require freeing memory, and/or altering the reference counts of specific objects based on your use.

int **PyArray_Converter** (PyObject *obj, PyObject **address)

Convert any Python object to a `PyArrayObject`. If `PyArray_Check(obj)` is TRUE then its reference count is incremented and a reference placed in `address`. If `obj` is not an array, then convert it to an array using `PyArray_FromAny`. No matter what is returned, you must DECREF the object returned by this routine in `address` when you are done with it.

int **PyArray_OutputConverter** (PyObject *obj, PyArrayObject **address)

This is a default converter for output arrays given to functions. If `obj` is `Py_None` or NULL, then `*address` will be NULL but the call will succeed. If `PyArray_Check(obj)` is TRUE then it is returned in `*address` without incrementing its reference count.

int **PyArray_IntpConverter** (PyObject *obj, PyArray_Dims *seq)

Convert any Python sequence, `obj`, smaller than `NPY_MAXDIMS` to a C-array of `numpy_intp`. The Python object could also be a single number. The `seq` variable is a pointer to a structure with members `ptr` and `len`. On successful return, `seq->ptr` contains a pointer to memory that must be freed, by calling `PyDimMem_FREE`, to avoid a memory leak. The restriction on memory size allows this converter to be conveniently used for sequences intended to be interpreted as array shapes.

int **PyArray_BufferConverter** (PyObject *obj, PyArray_Chunk *buf)

Convert any Python object, `obj`, with a (single-segment) buffer interface to a variable with members that detail the object's use of its chunk of memory. The `buf` variable is a pointer to a structure with base, ptr, len, and flags members. The `PyArray_Chunk` structure is binary compatible with the Python's buffer object (through its len member on 32-bit platforms and its ptr member on 64-bit platforms). On return, the base member is set to `obj` (or its base if `obj` is already a buffer object pointing to another object). If you need to hold on to the memory be sure to INCREASE the base member. The chunk of memory is pointed to by `buf->ptr` member and has length `buf->len`. The flags member of `buf` is `NPY_ARRAY_ALIGNED` with the `NPY_ARRAY_WRITEABLE` flag set if `obj` has a writeable buffer interface.

int **PyArray_AxisConverter** (PyObject *obj, int *axis)

Convert a Python object, `obj`, representing an axis argument to the proper value for passing to the functions that take an integer axis. Specifically, if `obj` is None, `axis` is set to `NPY_RAVEL_AXIS` which is interpreted correctly by the C-API functions that take axis arguments.

int **PyArray_BoolConverter** (PyObject *obj, numpy_bool *value)

Convert any Python object, `obj`, to `NPY_TRUE` or `NPY_FALSE`, and place the result in `value`.

int **PyArray_ByteorderConverter** (PyObject *obj, char *endian)

Convert Python strings into the corresponding byte-order character: '>', '<', 's', '=', or '|'.

int **PyArray_SortkindConverter** (PyObject *obj, NPY_SORTKIND *sort)

Convert Python strings into one of `NPY_QUICKSORT` (starts with 'q' or 'Q'), `NPY_HEAPSORT` (starts with 'h' or 'H'), `NPY_MERGESORT` (starts with 'm' or 'M') or `NPY_STABLESORT` (starts with 't' or 'T'). `NPY_MERGESORT`

and `NPY_STABLESORT` are aliased to each other for backwards compatibility and may refer to one of several stable sorting algorithms depending on the data type.

int **PyArray_SearchsideConverter** (PyObject *obj, `NPY_SEARCHSIDE` *side)

Convert Python strings into one of `NPY_SEARCHLEFT` (starts with 'l' or 'L'), or `NPY_SEARCHRIGHT` (starts with 'r' or 'R').

int **PyArray_OrderConverter** (PyObject *obj, `NPY_ORDER` *order)

Convert the Python strings 'C', 'F', 'A', and 'K' into the `NPY_ORDER` enumeration `NPY_CORDER`, `NPY_FORTRANORDER`, `NPY_ANYORDER`, and `NPY_KEEPOORDER`.

int **PyArray_CastingConverter** (PyObject *obj, `NPY_CASTING` *casting)

Convert the Python strings 'no', 'equiv', 'safe', 'same_kind', and 'unsafe' into the `NPY_CASTING` enumeration `NPY_NO_CASTING`, `NPY_EQUIV_CASTING`, `NPY_SAFE_CASTING`, `NPY_SAME_KIND_CASTING`, and `NPY_UNSAFE_CASTING`.

int **PyArray_ClipmodeConverter** (PyObject *object, `NPY_CLIPMODE` *val)

Convert the Python strings 'clip', 'wrap', and 'raise' into the `NPY_CLIPMODE` enumeration `NPY_CLIP`, `NPY_WRAP`, and `NPY_RAISE`.

int **PyArray_ConvertClipmodeSequence** (PyObject *object, `NPY_CLIPMODE` *modes, int n)

Converts either a sequence of clipmodes or a single clipmode into a C array of `NPY_CLIPMODE` values. The number of clipmodes *n* must be known before calling this function. This function is provided to help functions allow a different clipmode for each dimension.

Other conversions

int **PyArray_PyIntAsInt** (PyObject *op)

Convert all kinds of Python objects (including arrays and array scalars) to a standard integer. On error, -1 is returned and an exception set. You may find useful the macro:

```
#define error_converting(x) (((x) == -1) && PyErr_Occurred())
```

`numpy_intp` **PyArray_PyIntAsIntp** (PyObject *op)

Convert all kinds of Python objects (including arrays and array scalars) to a (platform-pointer-sized) integer. On error, -1 is returned and an exception set.

int **PyArray_IntpFromSequence** (PyObject *seq, `numpy_intp` *vals, int maxvals)

Convert any Python sequence (or single Python number) passed in as *seq* to (up to) *maxvals* pointer-sized integers and place them in the *vals* array. The sequence can be smaller than *maxvals* as the number of converted objects is returned.

Including and importing the C API

To use the NumPy C-API you typically need to include the `numpy/ndarrayobject.h` header and `numpy/ufuncobject.h` for some ufunc related functionality (`arrayobject.h` is an alias for `ndarrayobject.h`).

These two headers export most relevant functionality. In general any project which uses the NumPy API must import NumPy using one of the functions `PyArray_ImportNumPyAPI()` or `import_array()`. In some places, functionality which requires `import_array()` is not needed, because you only need type definitions. In this case, it is sufficient to include `numpy/ndarraytypes.h`.

For the typical Python project, multiple C or C++ files will be compiled into a single shared object (the Python C-module) and `PyArray_ImportNumPyAPI()` should be called inside its module initialization.

When you have a single C-file, this will consist of:

```
#include "numpy/ndarrayobject.h"

PyMODINIT_FUNC PyInit_my_module(void)
{
    if (PyArray_ImportNumPyAPI() < 0) {
        return NULL;
    }
    /* Other initialization code. */
}
```

However, most projects will have additional C files which are all linked together into a single Python module. In this case, the helper C files typically do not have a canonical place where `PyArray_ImportNumPyAPI` should be called (although it is OK and fast to call it often).

To solve this, NumPy provides the following pattern that the main file is modified to define `PY_ARRAY_UNIQUE_SYMBOL` before the include:

```
/* Main module file */
#define PY_ARRAY_UNIQUE_SYMBOL MyModule
#include "numpy/ndarrayobject.h"

PyMODINIT_FUNC PyInit_my_module(void)
{
    if (PyArray_ImportNumPyAPI() < 0) {
        return NULL;
    }
    /* Other initialization code. */
}
```

while the other files use:

```
/* Second file without any import */
#define NO_IMPORT_ARRAY
#define PY_ARRAY_UNIQUE_SYMBOL MyModule
#include "numpy/ndarrayobject.h"
```

You can of course add the defines to a local header used throughout. You just have to make sure that the main file does `_not_` define `NO_IMPORT_ARRAY`.

For `numpy/ufuncobject.h` the same logic applies, but the unique symbol mechanism is `#define PY_UFUNC_UNIQUE_SYMBOL` (both can match).

Additionally, you will probably wish to add a `#define NPY_NO_DEPRECATED_API NPY_1_7_API_VERSION` to avoid warnings about possible use of old API.

Note: If you are experiencing access violations make sure that the NumPy API was properly imported and the symbol `PyArray_API` is not NULL. When in a debugger, this symbols actual name will be `PY_ARRAY_UNIQUE_SYMBOL``+``PyArray_API`, so for example `MyModulePyArray_API` in the above. (E.g. even a `printf("%p\n", PyArray_API);` just before the crash.)

Mechanism details and dynamic linking

The main part of the mechanism is that without NumPy needs to define a `void **PyArray_API` table for you to look up all functions. Depending on your macro setup, this takes different routes depending on whether `NO_IMPORT_ARRAY` and `PY_ARRAY_UNIQUE_SYMBOL` are defined:

- If neither is defined, the C-API is declared to `static void **PyArray_API`, so it is only visible within the compilation unit/file using `#include <numpy/arrayobject.h>`.
- If only `PY_ARRAY_UNIQUE_SYMBOL` is defined (it could be empty) then the it is declared to a non-static `void **` allowing it to be used by other files which are linked.
- If `NO_IMPORT_ARRAY` is defined, the table is declared as `extern void **`, meaning that it must be linked to a file which does not use `NO_IMPORT_ARRAY`.

The `PY_ARRAY_UNIQUE_SYMBOL` mechanism additionally mangles the names to avoid conflicts.

Changed in version NumPy: 2.1 changed the headers to avoid sharing the table outside of a single shared object/dll (this was always the case on Windows). Please see `NPY_API_SYMBOL_ATTRIBUTE` for details.

In order to make use of the C-API from another extension module, the `import_array` function must be called. If the extension module is self-contained in a single `.c` file, then that is all that needs to be done. If, however, the extension module involves multiple files where the C-API is needed then some additional steps must be taken.

int `PyArray_ImportNumPyAPI` (void)

Ensures that the NumPy C-API is imported and usable. It returns 0 on success and -1 with an error set if NumPy couldn't be imported. While preferable to call it once at module initialization, this function is very light-weight if called multiple times.

New in version 2.0: This function is backported in the `numpy_2_compat.h` header.

import_array (void)

This function must be called in the initialization section of a module that will make use of the C-API. It imports the module where the function-pointer table is stored and points the correct variable to it. This macro includes a `return NULL;` on error, so that `PyArray_ImportNumPyAPI()` is preferable for custom error checking. You may also see use of `_import_array()` (a function, not a macro, but you may want to raise a better error if it fails) and the variations `import_array1(ret)` which customizes the return value.

PY_ARRAY_UNIQUE_SYMBOL

NPY_API_SYMBOL_ATTRIBUTE

New in version 2.1.

An additional symbol which can be used to share e.g. visibility beyond shared object boundaries. By default, NumPy adds the C visibility hidden attribute (if available): `void __attribute__((visibility("hidden"))) **PyArray_API;` You can change this by defining `NPY_API_SYMBOL_ATTRIBUTE`, which will make this: `void NPY_API_SYMBOL_ATTRIBUTE **PyArray_API;` (with additional name mangling via the unique symbol).

Adding an empty `#define NPY_API_SYMBOL_ATTRIBUTE` will have the same behavior as NumPy 1.x.

Note: Windows never had shared visibility although you can use this macro to achieve it. We generally discourage sharing beyond shared boundary lines since importing the array API includes NumPy version checks.

NO_IMPORT_ARRAY

Defining `NO_IMPORT_ARRAY` before the `ndarrayobject.h` include indicates that the NumPy C API import is handled in a different file and the include mechanism will not be added here. You must have one file without `NO_IMPORT_ARRAY` defined.

```
#define PY_ARRAY_UNIQUE_SYMBOL cool_ARRAY_API
#include <numpy/arrayobject.h>
```

On the other hand, coolhelper.c would contain at the top:

```
#define NO_IMPORT_ARRAY
#define PY_ARRAY_UNIQUE_SYMBOL cool_ARRAY_API
#include <numpy/arrayobject.h>
```

You can also put the common two last lines into an extension-local header file as long as you make sure that `NO_IMPORT_ARRAY` is #defined before #including that file.

Internally, these #defines work as follows:

- If neither is defined, the C-API is declared to be `static void**`, so it is only visible within the compilation unit that #includes `numpy/arrayobject.h`.
- If `PY_ARRAY_UNIQUE_SYMBOL` is #defined, but `NO_IMPORT_ARRAY` is not, the C-API is declared to be `void**`, so that it will also be visible to other compilation units.
- If `NO_IMPORT_ARRAY` is #defined, regardless of whether `PY_ARRAY_UNIQUE_SYMBOL` is, the C-API is declared to be `extern void**`, so it is expected to be defined in another compilation unit.
- Whenever `PY_ARRAY_UNIQUE_SYMBOL` is #defined, it also changes the name of the variable holding the C-API, which defaults to `PyArray_API`, to whatever the macro is #defined to.

Checking the API Version

Because python extensions are not used in the same way as usual libraries on most platforms, some errors cannot be automatically detected at build time or even runtime. For example, if you build an extension using a function available only for `numpy >= 1.3.0`, and you import the extension later with `numpy 1.2`, you will not get an import error (but almost certainly a segmentation fault when calling the function). That's why several functions are provided to check for `numpy` versions. The macros `NPY_VERSION` and `NPY_FEATURE_VERSION` corresponds to the `numpy` version used to build the extension, whereas the versions returned by the functions `PyArray_GetNDArrayCVersion` and `PyArray_GetNDArrayCFeatureVersion` corresponds to the runtime `numpy`'s version.

The rules for ABI and API compatibilities can be summarized as follows:

- Whenever `NPY_VERSION != PyArray_GetNDArrayCVersion()`, the extension has to be recompiled (ABI incompatibility).
- `NPY_VERSION == PyArray_GetNDArrayCVersion()` and `NPY_FEATURE_VERSION <= PyArray_GetNDArrayCFeatureVersion()` means backward compatible changes.

ABI incompatibility is automatically detected in every `numpy`'s version. API incompatibility detection was added in `numpy 1.4.0`. If you want to supported many different `numpy` versions with one extension binary, you have to build your extension with the lowest `NPY_FEATURE_VERSION` as possible.

NPY_VERSION

The current version of the ndarray object (check to see if this variable is defined to guarantee the `numpy/arrayobject.h` header is being used).

NPY_FEATURE_VERSION

The current version of the C-API.

unsigned int **PyArray_GetNDArrayCVersion** (void)

This just returns the value `NPY_VERSION`. `NPY_VERSION` changes whenever a backward incompatible change at the ABI level. Because it is in the C-API, however, comparing the output of this function from the value defined in the current header gives a way to test if the C-API has changed thus requiring a re-compilation of extension modules that use the C-API. This is automatically checked in the function `import_array`.

unsigned int **PyArray_GetNDArrayCFeatureVersion** (void)

This just returns the value `NPY_FEATURE_VERSION`. `NPY_FEATURE_VERSION` changes whenever the API changes (e.g. a function is added). A changed value does not always require a recompile.

Memory management

char ***PyDataMem_NEW** (size_t nbytes)

void **PyDataMem_FREE** (char *ptr)

char ***PyDataMem_RENEW** (void *ptr, size_t newbytes)

Functions to allocate, free, and reallocate memory. These are used internally to manage array data memory unless overridden.

numpy_intp ***PyDimMem_NEW** (int nd)

void **PyDimMem_FREE** (char *ptr)

numpy_intp ***PyDimMem_RENEW** (void *ptr, size_t newnd)

Macros to allocate, free, and reallocate dimension and strides memory.

void ***PyArray_malloc** (size_t nbytes)

void **PyArray_free** (void *ptr)

void ***PyArray_realloc** (*numpy_intp* *ptr, size_t nbytes)

These macros use different memory allocators, depending on the constant `NPY_USE_PYMEM`. The system malloc is used when `NPY_USE_PYMEM` is 0, if `NPY_USE_PYMEM` is 1, then the Python memory allocator is used.

NPY_USE_PYMEM

int **PyArray_ResolveWritebackIfCopy** (*PyArrayObject* *obj)

If `obj->flags` has `NPY_ARRAY_WRITEBACKIFCOPY`, this function clears the flags, `DECREF` s `obj->base` and makes it writeable, and sets `obj->base` to `NULL`. It then copies `obj->data` to `obj->base->data`, and returns the error state of the copy operation. This is the opposite of `PyArray_SetWritebackIfCopyBase`. Usually this is called once you are finished with `obj`, just before `Py_DECREF(obj)`. It may be called multiple times, or with `NULL` input. See also `PyArray_DiscardWritebackIfCopy`.

Returns 0 if nothing was done, -1 on error, and 1 if action was taken.

Threading support

These macros are only meaningful if `NPY_ALLOW_THREADS` evaluates `True` during compilation of the extension module. Otherwise, these macros are equivalent to whitespace. Python uses a single Global Interpreter Lock (GIL) for each Python process so that only a single thread may execute at a time (even on multi-cpu machines). When calling out to a compiled function that may take time to compute (and does not have side-effects for other threads like updated global variables), the GIL should be released so that other Python threads can run while the time-consuming calculations are performed. This can be accomplished using two groups of macros. Typically, if one macro in a group is used in a code block, all of them must be used in the same code block. `NPY_ALLOW_THREADS` is `true` (defined as 1) unless the build option `-Ddisable-threading` is set to `true` - in which case `NPY_ALLOW_THREADS` is `false` (0).

NPY_ALLOW_THREADS

Group 1

This group is used to call code that may take some time but does not use any Python C-API calls. Thus, the GIL should be released during its calculation.

NPY_BEGIN_ALLOW_THREADS

Equivalent to `Py_BEGIN_ALLOW_THREADS` except it uses `NPY_ALLOW_THREADS` to determine if the macro is replaced with white-space or not.

NPY_END_ALLOW_THREADS

Equivalent to `Py_END_ALLOW_THREADS` except it uses `NPY_ALLOW_THREADS` to determine if the macro is replaced with white-space or not.

NPY_BEGIN_THREADS_DEF

Place in the variable declaration area. This macro sets up the variable needed for storing the Python state.

NPY_BEGIN_THREADS

Place right before code that does not need the Python interpreter (no Python C-API calls). This macro saves the Python state and releases the GIL.

NPY_END_THREADS

Place right after code that does not need the Python interpreter. This macro acquires the GIL and restores the Python state from the saved variable.

void **NPY_BEGIN_THREADS_DESCR** (*PyArray_Descr* *dtype)

Useful to release the GIL only if *dtype* does not contain arbitrary Python objects which may need the Python interpreter during execution of the loop.

void **NPY_END_THREADS_DESCR** (*PyArray_Descr* *dtype)

Useful to regain the GIL in situations where it was released using the BEGIN form of this macro.

void **NPY_BEGIN_THREADS_THRESHOLDED** (int loop_size)

Useful to release the GIL only if *loop_size* exceeds a minimum threshold, currently set to 500. Should be matched with a `NPY_END_THREADS` to regain the GIL.

Group 2

This group is used to re-acquire the Python GIL after it has been released. For example, suppose the GIL has been released (using the previous calls), and then some path in the code (perhaps in a different subroutine) requires use of the Python C-API, then these macros are useful to acquire the GIL. These macros accomplish essentially a reverse of the previous three (acquire the LOCK saving what state it had) and then re-release it with the saved state.

NPY_ALLOW_C_API_DEF

Place in the variable declaration area to set up the necessary variable.

NPY_ALLOW_C_API

Place before code that needs to call the Python C-API (when it is known that the GIL has already been released).

NPY_DISABLE_C_API

Place after code that needs to call the Python C-API (to re-release the GIL).

Tip: Never use semicolons after the threading support macros.

Priority

NPY_PRIORITY

Default priority for arrays.

NPY_SUBTYPE_PRIORITY

Default subtype priority.

NPY_SCALAR_PRIORITY

Default scalar priority (very small)

double **PyArray_GetPriority** (PyObject *obj, double def)

Return the `__array_priority__` attribute (converted to a double) of *obj* or *def* if no attribute of that name exists. Fast returns that avoid the attribute lookup are provided for objects of type `PyArray_Type`.

Default buffers

NPY_BUFSIZE

Default size of the user-settable internal buffers.

NPY_MIN_BUFSIZE

Smallest size of user-settable internal buffers.

NPY_MAX_BUFSIZE

Largest size allowed for the user-settable buffers.

Other constants

NPY_NUM_FLOATTYPE

The number of floating-point types

NPY_MAXDIMS

The maximum number of dimensions that may be used by NumPy. This is set to 64 and was 32 before NumPy 2.

Note: We encourage you to avoid `NPY_MAXDIMS`. A future version of NumPy may wish to remove any dimension limitation (and thus the constant). The limitation was created so that NumPy can use stack allocations internally for scratch space.

If your algorithm has a reasonable maximum number of dimension you could check and use that locally.

NPY_MAXARGS

The maximum number of array arguments that can be used in some functions. This used to be 32 before NumPy 2 and is now 64. To continue to allow using it as a check whether a number of arguments is compatible ufuncs, this macro is now runtime dependent.

Note: We discourage any use of `NPY_MAXARGS` that isn't explicitly tied to checking for known NumPy limitations.

NPY_FALSE

Defined as 0 for use with Bool.

NPY_TRUE

Defined as 1 for use with Bool.

NPY_FAIL

The return value of failed converter functions which are called using the “O&” syntax in `PyArg_ParseTuple`-like functions.

NPY_SUCCEED

The return value of successful converter functions which are called using the “O&” syntax in `PyArg_ParseTuple`-like functions.

NPY_RAVEL_AXIS

Some NumPy functions (mainly the C-entrypoints for Python functions) have an `axis` argument. This macro may be passed for `axis=None`.

Note: This macro is NumPy version dependent at runtime. The value is now the minimum integer. However, on NumPy 1.x `NPY_MAXDIMS` was used (at the time set to 32).

Miscellaneous Macros

int **PyArray_SAMESHAPE** (*PyArrayObject* *a1, *PyArrayObject* *a2)

Evaluates as True if arrays *a1* and *a2* have the same shape.

PyArray_MAX (*a*, *b*)

Returns the maximum of *a* and *b*. If (*a*) or (*b*) are expressions they are evaluated twice.

PyArray_MIN (*a*, *b*)

Returns the minimum of *a* and *b*. If (*a*) or (*b*) are expressions they are evaluated twice.

void **PyArray_DiscardWritebackIfCopy** (*PyArrayObject* *obj)

If `obj->flags` has `NPY_ARRAY_WRITEBACKIFCOPY`, this function clears the flags, `DECREF`s `obj->base` and makes it writeable, and sets `obj->base` to NULL. In contrast to `PyArray_ResolveWritebackIfCopy` it makes no attempt to copy the data from `obj->base`. This undoes `PyArray_SetWritebackIfCopyBase`. Usually this is called after an error when you are finished with `obj`, just before `Py_DECREF(obj)`. It may be called multiple times, or with NULL input.

Enumerated Types

enum **NPY_SORTKIND**

A special variable-type which can take on different values to indicate the sorting algorithm being used. These algorithm types have not been treated strictly for some time, but rather treated as stable/not stable. In NumPy 2.4 they are replaced by requirements (see below), but done in a backwards compatible way. These values will continue to work, except that that `NPY_HEAPSORT` will do the same thing as `NPY_QUICKSORT`.

enumerator **NPY_QUICKSORT**

enumerator **NPY_HEAPSORT**

enumerator **NPY_MERGESORT**

enumerator **NPY_STABLESORT**

Used as an alias of `NPY_MERGESORT` and vice versa.

enumerator **NPY_NSORTS**

Defined to be the number of sorts. It is fixed at three by the need for backwards compatibility, and consequently `NPY_MERGESORT` and `NPY_STABLESORT` are aliased to each other and may refer to one of several stable sorting algorithms depending on the data type.

In NumPy 2.4 the algorithm names are replaced by requirements. You can still use the old values, a recompile is not needed, but they are reinterpreted such that

- `NPY_QUICKSORT` and `NPY_HEAPSORT` -> `NPY_SORT_DEFAULT`
- `NPY_MERGESORT` and `NPY_STABLE` -> `NPY_SORT_STABLE`

enumerator **`NPY_SORT_DEFAULT`**

The default sort for the type. For the NumPy builtin types it may be stable or not, but will be ascending and sort NaN types to the end. It is usually chosen for speed and/or low memory.

enumerator **`NPY_SORT_STABLE`**

(Requirement) Specifies that the sort must be stable.

enumerator **`NPY_SORT_DESCENDING`**

(Requirement) Specifies that the sort must be in descending order. This functionality is not yet implemented for any of the NumPy types and cannot yet be set from the Python interface.

enum **`NPY_SCALARKIND`**

A special variable type indicating the number of “kinds” of scalars distinguished in determining scalar-coercion rules. This variable can take on the values:

enumerator **`NPY_NOSCALAR`**

enumerator **`NPY_BOOL_SCALAR`**

enumerator **`NPY_INTPOS_SCALAR`**

enumerator **`NPY_INTNEG_SCALAR`**

enumerator **`NPY_FLOAT_SCALAR`**

enumerator **`NPY_COMPLEX_SCALAR`**

enumerator **`NPY_OBJECT_SCALAR`**

enumerator **`NPY_NSCALARKINDS`**

Defined to be the number of scalar kinds (not including `NPY_NOSCALAR`).

enum **`NPY_ORDER`**

An enumeration type indicating the element order that an array should be interpreted in. When a brand new array is created, generally only **`NPY_CORDER`** and **`NPY_FORTRANORDER`** are used, whereas when one or more inputs are provided, the order can be based on them.

enumerator **`NPY_ANYORDER`**

Fortran order if all the inputs are Fortran, C otherwise.

enumerator **`NPY_CORDER`**

C order.

enumerator **`NPY_FORTRANORDER`**

Fortran order.

enumerator **`NPY_KEEPOORDER`**

An order as close to the order of the inputs as possible, even if the input is in neither C nor Fortran order.

enum **`NPY_CLIPMODE`**

A variable type indicating the kind of clipping that should be applied in certain functions.

enumerator **NPY_RAISE**

The default for most operations, raises an exception if an index is out of bounds.

enumerator **NPY_CLIP**

Clips an index to the valid range if it is out of bounds.

enumerator **NPY_WRAP**

Wraps an index to the valid range if it is out of bounds.

enum **NPY_SEARCHSIDE**

A variable type indicating whether the index returned should be that of the first suitable location (if [NPY_SEARCHLEFT](#)) or of the last (if [NPY_SEARCHRIGHT](#)).

enumerator **NPY_SEARCHLEFT**

enumerator **NPY_SEARCHRIGHT**

enum **NPY_SELECTKIND**

A variable type indicating the selection algorithm being used.

enumerator **NPY_INTROSELECT**

enum **NPY_CASTING**

An enumeration type indicating how permissive data conversions should be. This is used by the iterator added in NumPy 1.6, and is intended to be used more broadly in a future version.

enumerator **NPY_NO_CASTING**

Only allow identical types.

enumerator **NPY_EQUIV_CASTING**

Allow identical and casts involving byte swapping.

enumerator **NPY_SAFE_CASTING**

Only allow casts which will not cause values to be rounded, truncated, or otherwise changed.

enumerator **NPY_SAME_KIND_CASTING**

Allow any safe casts, and casts between types of the same kind. For example, float64 -> float32 is permitted with this rule.

enumerator **NPY_UNSAFE_CASTING**

Allow any cast, no matter what kind of data loss may occur.

NPY_SAME_VALUE_CASTING

Error if any values change during a cast. Currently supported only in `ndarray.astype(... casting='same_value')`

New in version 2.4.

2.1.5 Array iterator API

Array iterator

The array iterator encapsulates many of the key features in `ufuncs`, allowing user code to support features like output parameters, preservation of memory layouts, and buffering of data with the wrong alignment or type, without requiring difficult coding.

This page documents the API for the iterator. The iterator is named `NpyIter` and functions are named `NpyIter_*`.

There is an *introductory guide to array iteration* which may be of interest for those using this C API. In many instances, testing out ideas by creating the iterator in Python is a good idea before writing the C iteration code.

Iteration example

The best way to become familiar with the iterator is to look at its usage within the NumPy codebase itself. For example, here is a slightly tweaked version of the code for `PyArray_CountNonzero`, which counts the number of non-zero elements in an array.

```

numpy_intp PyArray_CountNonzero(PyArrayObject* self)
{
    /* Nonzero boolean function */
    PyArray_NonzeroFunc* nonzero = PyArray_DESCR(self)->f->nonzero;

    NpyIter* iter;
    NpyIter_IterNextFunc *iternext;
    char** dataptr;
    numpy_intp nonzero_count;
    numpy_intp* strideptr,* innersizeptr;

    /* Handle zero-sized arrays specially */
    if (PyArray_SIZE(self) == 0) {
        return 0;
    }

    /*
     * Create and use an iterator to count the nonzeros.
     * flag NPY_ITER_READONLY
     *   - The array is never written to.
     * flag NPY_ITER_EXTERNAL_LOOP
     *   - Inner loop is done outside the iterator for efficiency.
     * flag NPY_ITER_NPY_ITER_REFS_OK
     *   - Reference types are acceptable.
     * order NPY_KEEPOORDER
     *   - Visit elements in memory order, regardless of strides.
     *     This is good for performance when the specific order
     *     elements are visited is unimportant.
     * casting NPY_NO_CASTING
     *   - No casting is required for this operation.
     */
    iter = NpyIter_New(self, NPY_ITER_READONLY|
                        NPY_ITER_EXTERNAL_LOOP|
                        NPY_ITER_REFS_OK,
                        NPY_KEEPOORDER, NPY_NO_CASTING,
                        NULL);
    if (iter == NULL) {
        return -1;
    }

    /*
     * The iternext function gets stored in a local variable
     * so it can be called repeatedly in an efficient manner.
     */
    iternext = NpyIter_GetIterNext(iter, NULL);
    if (iternext == NULL) {
        NpyIter_Deallocate(iter);
        return -1;
    }
}

```

(continues on next page)

(continued from previous page)

```

}
/* The location of the data pointer which the iterator may update */
dataptr = NpyIter_GetDataPtrArray(iter);
/* The location of the stride which the iterator may update */
strideptr = NpyIter_GetInnerStrideArray(iter);
/* The location of the inner loop size which the iterator may update */
innersizeptr = NpyIter_GetInnerLoopSizePtr(iter);

nonzero_count = 0;
do {
    /* Get the inner loop data/stride/count values */
    char* data = *dataptr;
    npy_intp stride = *strideptr;
    npy_intp count = *innersizeptr;

    /* This is a typical inner loop for NPY_ITER_EXTERNAL_LOOP */
    while (count-- > 0) {
        if (nonzero(data, self)) {
            ++nonzero_count;
        }
        data += stride;
    }

    /* Increment the iterator to the next inner loop */
} while (iternext(iter));

NpyIter_Deallocate(iter);

return nonzero_count;
}

```

Multi-iteration example

Here is a copy function using the iterator. The order parameter is used to control the memory layout of the allocated result, typically `NPY_KEEPOORDER` is desired.

```

PyObject *CopyArray(PyObject *arr, NPY_ORDER order)
{
    NpyIter *iter;
    NpyIter_IterNextFunc *iternext;
    PyObject *op[2], *ret;
    npy_uint32 flags;
    npy_uint32 op_flags[2];
    npy_intp itemsize, *innersizeptr, innerstride;
    char **dataptrarray;

    /*
     * No inner iteration - inner loop is handled by CopyArray code
     */
    flags = NPY_ITER_EXTERNAL_LOOP;
    /*
     * Tell the constructor to automatically allocate the output.
     * The data type of the output will match that of the input.
     */
    op[0] = arr;

```

(continues on next page)

(continued from previous page)

```

op[1] = NULL;
op_flags[0] = NPY_ITER_READONLY;
op_flags[1] = NPY_ITER_WRITEONLY | NPY_ITER_ALLOCATE;

/* Construct the iterator */
iter = NpyIter_MultiNew(2, op, flags, order, NPY_NO_CASTING,
                        op_flags, NULL);

if (iter == NULL) {
    return NULL;
}

/*
 * Make a copy of the iternext function pointer and
 * a few other variables the inner loop needs.
 */
iternext = NpyIter_GetIterNext(iter, NULL);
innerstride = NpyIter_GetInnerStrideArray(iter)[0];
itemsize = NpyIter_GetDescrArray(iter)[0]->elsize;
/*
 * The inner loop size and data pointers may change during the
 * loop, so just cache the addresses.
 */
innersizeptr = NpyIter_GetInnerLoopSizePtr(iter);
dataptrarray = NpyIter_GetDataPtrArray(iter);

/*
 * Note that because the iterator allocated the output,
 * it matches the iteration order and is packed tightly,
 * so we don't need to check it like the input.
 */
if (innerstride == itemsize) {
    do {
        memcpy(dataptrarray[1], dataptrarray[0],
               itemsize * (*innersizeptr));
    } while (iternext(iter));
} else {
    /* For efficiency, should specialize this based on item size... */
    npy_intp i;
    do {
        npy_intp size = *innersizeptr;
        char *src = dataptrarray[0], *dst = dataptrarray[1];
        for(i = 0; i < size; i++, src += innerstride, dst += itemsize) {
            memcpy(dst, src, itemsize);
        }
    } while (iternext(iter));
}

/* Get the result from the iterator object array */
ret = NpyIter_GetOperandArray(iter)[1];
Py_INCREF(ret);

if (NpyIter_Deallocate(iter) != NPY_SUCCEED) {
    Py_DECREF(ret);
    return NULL;
}

return ret;

```

(continued from previous page)

}

Multi index tracking example

This example shows you how to work with the `NPY_ITER_MULTI_INDEX` flag. For simplicity, we assume the argument is a two-dimensional array.

```
int PrintMultiIndex(PyArrayObject *arr) {
    NpyIter *iter;
    NpyIter_IterNextFunc *iternext;
    npy_intp multi_index[2];

    iter = NpyIter_New(
        arr, NPY_ITER_READONLY | NPY_ITER_MULTI_INDEX | NPY_ITER_REFS_OK,
        NPY_KEEPOORDER, NPY_NO_CASTING, NULL);
    if (iter == NULL) {
        return -1;
    }
    if (NpyIter_GetNDim(iter) != 2) {
        NpyIter_Deallocate(iter);
        PyErr_SetString(PyExc_ValueError, "Array must be 2-D");
        return -1;
    }
    if (NpyIter_GetIterSize(iter) != 0) {
        iternext = NpyIter_GetIterNext(iter, NULL);
        if (iternext == NULL) {
            NpyIter_Deallocate(iter);
            return -1;
        }
        NpyIter_GetMultiIndexFunc *get_multi_index =
            NpyIter_GetGetMultiIndex(iter, NULL);
        if (get_multi_index == NULL) {
            NpyIter_Deallocate(iter);
            return -1;
        }

        do {
            get_multi_index(iter, multi_index);
            printf("multi_index is [%s NPY_INTF_FMT ", %s NPY_INTF_FMT "]\n",
                multi_index[0], multi_index[1]);
        } while (iternext(iter));
    }
    if (!NpyIter_Deallocate(iter)) {
        return -1;
    }
    return 0;
}
```

When called with a 2x3 array, the above example prints:

```
multi_index is [0, 0]
multi_index is [0, 1]
multi_index is [0, 2]
multi_index is [1, 0]
```

(continues on next page)

(continued from previous page)

```
multi_index is [1, 1]
multi_index is [1, 2]
```

Iterator data types

The iterator layout is an internal detail, and user code only sees an incomplete struct.

type **NpyIter**

This is an opaque pointer type for the iterator. Access to its contents can only be done through the iterator API.

type **NpyIter_Type**

This is the type which exposes the iterator to Python. Currently, no API is exposed which provides access to the values of a Python-created iterator. If an iterator is created in Python, it must be used in Python and vice versa. Such an API will likely be created in a future version.

type **NpyIter_IterNextFunc**

This is a function pointer for the iteration loop, returned by *NpyIter_GetIterNext*.

type **NpyIter_GetMultiIndexFunc**

This is a function pointer for getting the current iterator multi-index, returned by *NpyIter_GetMultiIndex*.

Construction and destruction

NpyIter ***NpyIter_New** (*PyArrayObject* *op, *numpy_uint32* flags, *NPY_ORDER* order, *NPY_CASTING* casting, *PyArray_Descr* *dtype)

Creates an iterator for the given numpy array object op.

Flags that may be passed in flags are any combination of the global and per-operand flags documented in *NpyIter_MultiNew*, except for *NPY_ITER_ALLOCATE*.

Any of the *NPY_ORDER* enum values may be passed to order. For efficient iteration, *NPY_KEEPOORDER* is the best option, and the other orders enforce the particular iteration pattern.

Any of the *NPY_CASTING* enum values may be passed to casting. The values include *NPY_NO_CASTING*, *NPY_EQUIV_CASTING*, *NPY_SAFE_CASTING*, *NPY_SAME_KIND_CASTING*, and *NPY_UNSAFE_CASTING*. To allow the casts to occur, copying or buffering must also be enabled.

If dtype isn't NULL, then it requires that data type. If copying is allowed, it will make a temporary copy if the data is castable. If *NPY_ITER_UPDATEIFCOPY* is enabled, it will also copy the data back with another cast upon iterator destruction.

Returns NULL if there is an error, otherwise returns the allocated iterator.

To make an iterator similar to the old iterator, this should work.

```
iter = NpyIter_New(op, NPY_ITER_READWRITE,
                  NPY_CORDER, NPY_NO_CASTING, NULL);
```

If you want to edit an array with aligned double code, but the order doesn't matter, you would use this.

```
dtype = PyArray_DescrFromType(NPY_DOUBLE);
iter = NpyIter_New(op, NPY_ITER_READWRITE |
                  NPY_ITER_BUFFERED |
                  NPY_ITER_NBO |
```

(continues on next page)

(continued from previous page)

```

        NPY_ITER_ALIGNED,
        NPY_KEEPOORDER,
        NPY_SAME_KIND_CASTING,
        dtype);
Py_DECREF(dtype);

```

NpyIter ***NpyIter_MultiNew** (*npy_intp* nop, *PyArrayObject* **op, *npy_uint32* flags, *NPY_ORDER* order, *NPY_CASTING* casting, *npy_uint32* *op_flags, *PyArray_Descr* **op_dtypes)

Creates an iterator for broadcasting the nop array objects provided in op, using regular NumPy broadcasting rules.

Any of the *NPY_ORDER* enum values may be passed to order. For efficient iteration, *NPY_KEEPOORDER* is the best option, and the other orders enforce the particular iteration pattern. When using *NPY_KEEPOORDER*, if you also want to ensure that the iteration is not reversed along an axis, you should pass the flag *NPY_ITER_DONT_NEGATE_STRIDES*.

Any of the *NPY_CASTING* enum values may be passed to casting. The values include *NPY_NO_CASTING*, *NPY_EQUIV_CASTING*, *NPY_SAFE_CASTING*, *NPY_SAME_KIND_CASTING*, and *NPY_UNSAFE_CASTING*. To allow the casts to occur, copying or buffering must also be enabled.

If op_dtypes isn't NULL, it specifies a data type or NULL for each op[i].

Returns NULL if there is an error, otherwise returns the allocated iterator.

Flags that may be passed in flags, applying to the whole iterator, are:

NPY_ITER_C_INDEX

Causes the iterator to track a raveled flat index matching C order. This option cannot be used with *NPY_ITER_F_INDEX*.

NPY_ITER_F_INDEX

Causes the iterator to track a raveled flat index matching Fortran order. This option cannot be used with *NPY_ITER_C_INDEX*.

NPY_ITER_MULTI_INDEX

Causes the iterator to track a multi-index. This prevents the iterator from coalescing axes to produce bigger inner loops. If the loop is also not buffered and no index is being tracked (*NpyIter_RemoveAxis* can be called), then the iterator size can be -1 to indicate that the iterator is too large. This can happen due to complex broadcasting and will result in errors being created when the setting the iterator range, removing the multi index, or getting the next function. However, it is possible to remove axes again and use the iterator normally if the size is small enough after removal.

NPY_ITER_EXTERNAL_LOOP

Causes the iterator to skip iteration of the innermost loop, requiring the user of the iterator to handle it.

This flag is incompatible with *NPY_ITER_C_INDEX*, *NPY_ITER_F_INDEX*, and *NPY_ITER_MULTI_INDEX*.

NPY_ITER_DONT_NEGATE_STRIDES

This only affects the iterator when *NPY_KEEPOORDER* is specified for the order parameter. By default with *NPY_KEEPOORDER*, the iterator reverses axes which have negative strides, so that memory is traversed in a forward direction. This disables this step. Use this flag if you want to use the underlying memory-ordering of the axes, but don't want an axis reversed. This is the behavior of `numpy.ravel(a, order='K')`, for instance.

NPY_ITER_COMMON_DTYPE

Causes the iterator to convert all the operands to a common data type, calculated based on the ufunc type promotion rules. Copying or buffering must be enabled.

If the common data type is known ahead of time, don't use this flag. Instead, set the requested dtype for all the operands.

NPY_ITER_REFS_OK

Indicates that arrays with reference types (object arrays or structured arrays containing an object type) may be accepted and used in the iterator. If this flag is enabled, the caller must be sure to check whether `NpyIter_IterationNeedsAPI(iter)` is true, in which case it may not release the GIL during iteration. If you are working with known dtypes `NpyIter_GetTransferFlags` is a faster and more precise way to check for whether the iterator needs the API due to buffering.

NPY_ITER_ZEROSIZE_OK

Indicates that arrays with a size of zero should be permitted. Since the typical iteration loop does not naturally work with zero-sized arrays, you must check that the `IterSize` is larger than zero before entering the iteration loop. Currently only the operands are checked, not a forced shape.

NPY_ITER_REDUCE_OK

Permits writeable operands with a dimension with zero stride and size greater than one. Note that such operands must be read/write.

When buffering is enabled, this also switches to a special buffering mode which reduces the loop length as necessary to not trample on values being reduced.

Note that if you want to do a reduction on an automatically allocated output, you must use `NpyIter_GetOperandArray` to get its reference, then set every value to the reduction unit before doing the iteration loop. In the case of a buffered reduction, this means you must also specify the flag `NPY_ITER_DELAY_BUFALLOC`, then reset the iterator after initializing the allocated operand to prepare the buffers.

NPY_ITER_RANGED

Enables support for iteration of sub-ranges of the full `iterindex` range `[0, NpyIter_IterSize(iter))`. Use the function `NpyIter_ResetToIterIndexRange` to specify a range for iteration.

This flag can only be used with `NPY_ITER_EXTERNAL_LOOP` when `NPY_ITER_BUFFERED` is enabled. This is because without buffering, the inner loop is always the size of the innermost iteration dimension, and allowing it to get cut up would require special handling, effectively making it more like the buffered version.

NPY_ITER_BUFFERED

Causes the iterator to store buffering data, and use buffering to satisfy data type, alignment, and byte-order requirements. To buffer an operand, do not specify the `NPY_ITER_COPY` or `NPY_ITER_UPDATEIFCOPY` flags, because they will override buffering. Buffering is especially useful for Python code using the iterator, allowing for larger chunks of data at once to amortize the Python interpreter overhead.

If used with `NPY_ITER_EXTERNAL_LOOP`, the inner loop for the caller may get larger chunks than would be possible without buffering, because of how the strides are laid out.

Note that if an operand is given the flag `NPY_ITER_COPY` or `NPY_ITER_UPDATEIFCOPY`, a copy will be made in preference to buffering. Buffering will still occur when the array was broadcast so elements need to be duplicated to get a constant stride.

In normal buffering, the size of each inner loop is equal to the buffer size, or possibly larger if `NPY_ITER_GROWINNER` is specified. If `NPY_ITER_REDUCE_OK` is enabled and a reduction occurs, the inner loops may become smaller depending on the structure of the reduction.

NPY_ITER_GROWINNER

When buffering is enabled, this allows the size of the inner loop to grow when buffering isn't necessary. This option is best used if you're doing a straight pass through all the data, rather than anything with small cache-friendly arrays of temporary values for each inner loop.

NPY_ITER_DELAY_BUFALLOC

When buffering is enabled, this delays allocation of the buffers until *NpyIter_Reset* or another reset function is called. This flag exists to avoid wasteful copying of buffer data when making multiple copies of a buffered iterator for multi-threaded iteration.

Another use of this flag is for setting up reduction operations. After the iterator is created, and a reduction output is allocated automatically by the iterator (be sure to use READWRITE access), its value may be initialized to the reduction unit. Use *NpyIter_GetOperandArray* to get the object. Then, call *NpyIter_Reset* to allocate and fill the buffers with their initial values.

NPY_ITER_COPY_IF_OVERLAP

If any write operand has overlap with any read operand, eliminate all overlap by making temporary copies (enabling UPDATEIFCOPY for write operands, if necessary). A pair of operands has overlap if there is a memory address that contains data common to both arrays.

Because exact overlap detection has exponential runtime in the number of dimensions, the decision is made based on heuristics, which has false positives (needless copies in unusual cases) but has no false negatives.

If any read/write overlap exists, this flag ensures the result of the operation is the same as if all operands were copied. In cases where copies would need to be made, **the result of the computation may be undefined without this flag!**

Flags that may be passed in `op_flags[i]`, where $0 \leq i < \text{nop}$:

NPY_ITER_READWRITE**NPY_ITER_READONLY****NPY_ITER_WRITEONLY**

Indicate how the user of the iterator will read or write to `op[i]`. Exactly one of these flags must be specified per operand. Using `NPY_ITER_READWRITE` or `NPY_ITER_WRITEONLY` for a user-provided operand may trigger `WRITEBACKIFCOPY` semantics. The data will be written back to the original array when *NpyIter_Deallocate* is called.

NPY_ITER_COPY

Allow a copy of `op[i]` to be made if it does not meet the data type or alignment requirements as specified by the constructor flags and parameters.

NPY_ITER_UPDATEIFCOPY

Triggers *NPY_ITER_COPY*, and when an array operand is flagged for writing and is copied, causes the data in a copy to be copied back to `op[i]` when *NpyIter_Deallocate* is called.

If the operand is flagged as write-only and a copy is needed, an uninitialized temporary array will be created and then copied to back to `op[i]` on calling *NpyIter_Deallocate*, instead of doing the unnecessary copy operation.

NPY_ITER_NBO**NPY_ITER_ALIGNED****NPY_ITER_CONTIG**

Causes the iterator to provide data for `op[i]` that is in native byte order, aligned according to the dtype requirements, contiguous, or any combination.

By default, the iterator produces pointers into the arrays provided, which may be aligned or unaligned, and with any byte order. If copying or buffering is not enabled and the operand data doesn't satisfy the constraints, an error will be raised.

The contiguous constraint applies only to the inner loop, successive inner loops may have arbitrary pointer changes.

If the requested data type is in non-native byte order, the NBO flag overrides it and the requested data type is converted to be in native byte order.

NPY_ITER_ALLOCATE

This is for output arrays, and requires that the flag `NPY_ITER_WRITEONLY` or `NPY_ITER_READWRITE` be set. If `op[i]` is NULL, creates a new array with the final broadcast dimensions, and a layout matching the iteration order of the iterator.

When `op[i]` is NULL, the requested data type `op_dtypes[i]` may be NULL as well, in which case it is automatically generated from the dtypes of the arrays which are flagged as readable. The rules for generating the dtype are the same as for UFuncs. Of special note is handling of byte order in the selected dtype. If there is exactly one input, the input's dtype is used as is. Otherwise, if more than one input dtypes are combined together, the output will be in native byte order.

After being allocated with this flag, the caller may retrieve the new array by calling `NpyIter_GetOperandArray` and getting the *i*-th object in the returned C array. The caller must call `Py_INCREF` on it to claim a reference to the array.

NPY_ITER_NO_SUBTYPE

For use with `NPY_ITER_ALLOCATE`, this flag disables allocating an array subtype for the output, forcing it to be a straight ndarray.

TODO: Maybe it would be better to introduce a function `NpyIter_GetWrappedOutput` and remove this flag?

NPY_ITER_NO_BROADCAST

Ensures that the input or output matches the iteration dimensions exactly.

NPY_ITER_ARRAYMASK

Indicates that this operand is the mask to use for selecting elements when writing to operands which have the `NPY_ITER_WRITEMASKED` flag applied to them. Only one operand may have `NPY_ITER_ARRAYMASK` flag applied to it.

The data type of an operand with this flag should be either `NPY_BOOL`, `NPY_MASK`, or a struct dtype whose fields are all valid mask dtypes. In the latter case, it must match up with a struct operand being `WRITEMASKED`, as it is specifying a mask for each field of that array.

This flag only affects writing from the buffer back to the array. This means that if the operand is also `NPY_ITER_READWRITE` or `NPY_ITER_WRITEONLY`, code doing iteration can write to this operand to control which elements will be untouched and which ones will be modified. This is useful when the mask should be a combination of input masks.

NPY_ITER_WRITEMASKED

This array is the mask for all *writemasked* operands. Code uses the `writemasked` flag which indicates that only elements where the chosen `ARRAYMASK` operand is True will be written to. In general, the iterator does not enforce this, it is up to the code doing the iteration to follow that promise.

When `writemasked` flag is used, and this operand is buffered, this changes how data is copied from the buffer into the array. A masked copying routine is used, which only copies the elements in the buffer for which `writemasked` returns true from the corresponding element in the `ARRAYMASK` operand.

NPY_ITER_OVERLAP_ASSUME_ELEMENTWISE

In memory overlap checks, assume that operands with `NPY_ITER_OVERLAP_ASSUME_ELEMENTWISE` enabled are accessed only in the iterator order.

This enables the iterator to reason about data dependency, possibly avoiding unnecessary copies.

This flag has effect only if `NPY_ITER_COPY_IF_OVERLAP` is enabled on the iterator.

NpyIter ***NpyIter_AdvancedNew** (*numpy_intp* nop, *PyArrayObject* **op, *numpy_uint32* flags, *NPY_ORDER* order, *NPY_CASTING* casting, *numpy_uint32* *op_flags, *PyArray_Descr* **op_dtypes, int oa_ndim, int **op_axes, *numpy_intp* const *itershape, *numpy_intp* buffersize)

Extends *NpyIter_MultiNew* with several advanced options providing more control over broadcasting and buffering.

If -1/NULL values are passed to oa_ndim, op_axes, itershape, and buffersize, it is equivalent to *NpyIter_MultiNew*.

The parameter oa_ndim, when not zero or -1, specifies the number of dimensions that will be iterated with customized broadcasting. If it is provided, op_axes must and itershape can also be provided. The op_axes parameter let you control in detail how the axes of the operand arrays get matched together and iterated. In op_axes, you must provide an array of nop pointers to oa_ndim-sized arrays of type *numpy_intp*. If an entry in op_axes is NULL, normal broadcasting rules will apply. In op_axes[j][i] is stored either a valid axis of op[j], or -1 which means newaxis. Within each op_axes[j] array, axes may not be repeated. The following example is how normal broadcasting applies to a 3-D array, a 2-D array, a 1-D array and a scalar.

Note: Before NumPy 1.8 oa_ndim == 0 was used for signalling that op_axes and itershape are unused. This is deprecated and should be replaced with -1. Better backward compatibility may be achieved by using *NpyIter_MultiNew* for this case.

```
int oa_ndim = 3;           /* # iteration axes */
int op0_axes[] = {0, 1, 2}; /* 3-D operand */
int op1_axes[] = {-1, 0, 1}; /* 2-D operand */
int op2_axes[] = {-1, -1, 0}; /* 1-D operand */
int op3_axes[] = {-1, -1, -1} /* 0-D (scalar) operand */
int* op_axes[] = {op0_axes, op1_axes, op2_axes, op3_axes};
```

The itershape parameter allows you to force the iterator to have a specific iteration shape. It is an array of length oa_ndim. When an entry is negative, its value is determined from the operands. This parameter allows automatically allocated outputs to get additional dimensions which don't match up with any dimension of an input.

If buffersize is zero, a default buffer size is used, otherwise it specifies how big of a buffer to use. Buffers which are powers of 2 such as 4096 or 8192 are recommended.

Returns NULL if there is an error, otherwise returns the allocated iterator.

NpyIter ***NpyIter_Copy** (*NpyIter* *iter)

Makes a copy of the given iterator. This function is provided primarily to enable multi-threaded iteration of the data.

TODO: Move this to a section about multithreaded iteration.

The recommended approach to multithreaded iteration is to first create an iterator with the flags *NPY_ITER_EXTERNAL_LOOP*, *NPY_ITER_RANGED*, *NPY_ITER_BUFFERED*, *NPY_ITER_DELAY_BUFALLOC*, and possibly *NPY_ITER_GROWINNER*. Create a copy of this iterator for each thread (minus one for the first iterator). Then, take the iteration index range [0, *NpyIter_GetIterSize*(iter)) and split it up into tasks, for example using a TBB parallel_for loop. When a thread gets a task to execute, it then uses its copy of the iterator by calling *NpyIter_ResetToIterIndexRange* and iterating over the full range.

When using the iterator in multi-threaded code or in code not holding the Python GIL, care must be taken to only call functions which are safe in that context. *NpyIter_Copy* cannot be safely called without the Python GIL, because it increments Python references. The *Reset** and some other functions may be safely called by passing in the *errmsg* parameter as non-NULL, so that the functions will pass back errors through it instead of setting a Python exception.

NpyIter_Deallocate must be called for each copy.

int **NpyIter_RemoveAxis** (*NpyIter* *iter, int axis)

Removes an axis from iteration. This requires that `NPY_ITER_MULTI_INDEX` was set for iterator creation, and does not work if buffering is enabled or an index is being tracked. This function also resets the iterator to its initial state.

This is useful for setting up an accumulation loop, for example. The iterator can first be created with all the dimensions, including the accumulation axis, so that the output gets created correctly. Then, the accumulation axis can be removed, and the calculation done in a nested fashion.

WARNING: This function may change the internal memory layout of the iterator. Any cached functions or pointers from the iterator must be retrieved again! The iterator range will be reset as well.

Returns `NPY_SUCCEED` or `NPY_FAIL`.

int **NpyIter_RemoveMultiIndex** (*NpyIter* *iter)

If the iterator is tracking a multi-index, this strips support for them, and does further iterator optimizations that are possible if multi-indices are not needed. This function also resets the iterator to its initial state.

WARNING: This function may change the internal memory layout of the iterator. Any cached functions or pointers from the iterator must be retrieved again!

After calling this function, `NpyIter_HasMultiIndex(iter)` will return false.

Returns `NPY_SUCCEED` or `NPY_FAIL`.

int **NpyIter_EnableExternalLoop** (*NpyIter* *iter)

If `NpyIter_RemoveMultiIndex` was called, you may want to enable the flag `NPY_ITER_EXTERNAL_LOOP`. This flag is not permitted together with `NPY_ITER_MULTI_INDEX`, so this function is provided to enable the feature after `NpyIter_RemoveMultiIndex` is called. This function also resets the iterator to its initial state.

WARNING: This function changes the internal logic of the iterator. Any cached functions or pointers from the iterator must be retrieved again!

Returns `NPY_SUCCEED` or `NPY_FAIL`.

int **NpyIter_Deallocate** (*NpyIter* *iter)

Deallocates the iterator object and resolves any needed writebacks.

Returns `NPY_SUCCEED` or `NPY_FAIL`.

`NPY_ARRAYMETHOD_FLAGS` **NpyIter_GetTransferFlags** (*NpyIter* *iter)

New in version 2.3.

Fetches the `NPY_METH_RUNTIME_FLAGS` which provide the information on whether buffering needs the Python GIL (`NPY_METH_REQUIRES_PYAPI`) or floating point errors may be set (`NPY_METH_NO_FLOATINGPOINT_ERRORS`).

Prior to NumPy 2.3, the public function available was `NpyIter_IterationNeedsAPI`, which is still available and additionally checks for object (or similar) dtypes and not exclusively for buffering/iteration needs itself. In general, this function should be preferred.

int **NpyIter_Reset** (*NpyIter* *iter, char **errmsg)

Resets the iterator back to its initial state, at the beginning of the iteration range.

Returns `NPY_SUCCEED` or `NPY_FAIL`. If `errmsg` is non-NULL, no Python exception is set when `NPY_FAIL` is returned. Instead, `*errmsg` is set to an error message. When `errmsg` is non-NULL, the function may be safely called without holding the Python GIL.

int **NpyIter_ResetToIterIndexRange** (*NpyIter* *iter, *numpy_intp* istart, *numpy_intp* iend, char **errmsg)

Resets the iterator and restricts it to the `iterindex` range [`istart`, `iend`). See [NpyIter_Copy](#) for an explanation of how to use this for multi-threaded iteration. This requires that the flag `NPY_ITER_RANGED` was passed to the iterator constructor.

If you want to reset both the `iterindex` range and the base pointers at the same time, you can do the following to avoid extra buffer copying (be sure to add the return code error checks when you copy this code).

```
/* Set to a trivial empty range */
NpyIter_ResetToIterIndexRange(iter, 0, 0);
/* Set the base pointers */
NpyIter_ResetBasePointers(iter, baseptrs);
/* Set to the desired range */
NpyIter_ResetToIterIndexRange(iter, istart, iend);
```

Returns `NPY_SUCCEED` or `NPY_FAIL`. If `errmsg` is non-NULL, no Python exception is set when `NPY_FAIL` is returned. Instead, `*errmsg` is set to an error message. When `errmsg` is non-NULL, the function may be safely called without holding the Python GIL.

int **NpyIter_ResetBasePointers** (*NpyIter* *iter, char **baseptrs, char **errmsg)

Resets the iterator back to its initial state, but using the values in `baseptrs` for the data instead of the pointers from the arrays being iterated. This functions is intended to be used, together with the `op_axes` parameter, by nested iteration code with two or more iterators.

Returns `NPY_SUCCEED` or `NPY_FAIL`. If `errmsg` is non-NULL, no Python exception is set when `NPY_FAIL` is returned. Instead, `*errmsg` is set to an error message. When `errmsg` is non-NULL, the function may be safely called without holding the Python GIL.

TODO: Move the following into a special section on nested iterators.

Creating iterators for nested iteration requires some care. All the iterator operands must match exactly, or the calls to [NpyIter_ResetBasePointers](#) will be invalid. This means that automatic copies and output allocation should not be used haphazardly. It is possible to still use the automatic data conversion and casting features of the iterator by creating one of the iterators with all the conversion parameters enabled, then grabbing the allocated operands with the [NpyIter_GetOperandArray](#) function and passing them into the constructors for the rest of the iterators.

WARNING: When creating iterators for nested iteration, the code must not use a dimension more than once in the different iterators. If this is done, nested iteration will produce out-of-bounds pointers during iteration.

WARNING: When creating iterators for nested iteration, buffering can only be applied to the innermost iterator. If a buffered iterator is used as the source for `baseptrs`, it will point into a small buffer instead of the array and the inner iteration will be invalid.

The pattern for using nested iterators is as follows.

```
NpyIter *iter1, *iter1;
NpyIter_IterNextFunc *iternext1, *iternext2;
char **dataptrs1;

/*
 * With the exact same operands, no copies allowed, and
 * no axis in op_axes used both in iter1 and iter2.
 * Buffering may be enabled for iter2, but not for iter1.
 */
iter1 = ...; iter2 = ...;

iternext1 = NpyIter_GetIterNext(iter1);
iternext2 = NpyIter_GetIterNext(iter2);
```

(continues on next page)

(continued from previous page)

```

dataptrs1 = NpyIter_GetDataPtrArray(iter1);

do {
    NpyIter_ResetBasePointers(iter2, dataptrs1);
    do {
        /* Use the iter2 values */
    } while (iternext2(iter2));
} while (iternext1(iter1));

```

int **NpyIter_GotoMultiIndex** (*NpyIter* *iter, *numpy_intp* const *multi_index)

Adjusts the iterator to point to the ndim indices pointed to by *multi_index*. Returns an error if a multi-index is not being tracked, the indices are out of bounds, or inner loop iteration is disabled.

Returns NPY_SUCCEED or NPY_FAIL.

int **NpyIter_GotoIndex** (*NpyIter* *iter, *numpy_intp* index)

Adjusts the iterator to point to the *index* specified. If the iterator was constructed with the flag *NPY_ITER_C_INDEX*, *index* is the C-order index, and if the iterator was constructed with the flag *NPY_ITER_F_INDEX*, *index* is the Fortran-order index. Returns an error if there is no index being tracked, the index is out of bounds, or inner loop iteration is disabled.

Returns NPY_SUCCEED or NPY_FAIL.

numpy_intp **NpyIter_GetIterSize** (*NpyIter* *iter)

Returns the number of elements being iterated. This is the product of all the dimensions in the shape. When a multi index is being tracked (and *NpyIter_RemoveAxis* may be called) the size may be -1 to indicate an iterator is too large. Such an iterator is invalid, but may become valid after *NpyIter_RemoveAxis* is called. It is not necessary to check for this case.

numpy_intp **NpyIter_GetIterIndex** (*NpyIter* *iter)

Gets the *iterindex* of the iterator, which is an index matching the iteration order of the iterator.

void **NpyIter_GetIterIndexRange** (*NpyIter* *iter, *numpy_intp* *istart, *numpy_intp* *iend)

Gets the *iterindex* sub-range that is being iterated. If *NPY_ITER_RANGED* was not specified, this always returns the range [0, *NpyIter_IterSize*(iter)).

int **NpyIter_GotoIterIndex** (*NpyIter* *iter, *numpy_intp* iterindex)

Adjusts the iterator to point to the *iterindex* specified. The *IterIndex* is an index matching the iteration order of the iterator. Returns an error if the *iterindex* is out of bounds, buffering is enabled, or inner loop iteration is disabled.

Returns NPY_SUCCEED or NPY_FAIL.

numpy_bool **NpyIter_HasDelayedBufAlloc** (*NpyIter* *iter)

Returns 1 if the flag *NPY_ITER_DELAY_BUFALLOC* was passed to the iterator constructor, and no call to one of the Reset functions has been done yet, 0 otherwise.

numpy_bool **NpyIter_HasExternalLoop** (*NpyIter* *iter)

Returns 1 if the caller needs to handle the inner-most 1-dimensional loop, or 0 if the iterator handles all looping. This is controlled by the constructor flag *NPY_ITER_EXTERNAL_LOOP* or *NpyIter_EnableExternalLoop*.

numpy_bool **NpyIter_HasMultiIndex** (*NpyIter* *iter)

Returns 1 if the iterator was created with the *NPY_ITER_MULTI_INDEX* flag, 0 otherwise.

numpy_bool **NpyIter_HasIndex** (*NpyIter* *iter)

Returns 1 if the iterator was created with the *NPY_ITER_C_INDEX* or *NPY_ITER_F_INDEX* flag, 0 otherwise.

numpy_bool **NpyIter_RequiresBuffering** (*NpyIter* *iter)

Returns 1 if the iterator requires buffering, which occurs when an operand needs conversion or alignment and so cannot be used directly.

numpy_bool **NpyIter_IsBuffered** (*NpyIter* *iter)

Returns 1 if the iterator was created with the *NPY_ITER_BUFFERED* flag, 0 otherwise.

numpy_bool **NpyIter_IsGrowInner** (*NpyIter* *iter)

Returns 1 if the iterator was created with the *NPY_ITER_GROWINNER* flag, 0 otherwise.

numpy_intp **NpyIter_GetBufferSize** (*NpyIter* *iter)

If the iterator is buffered, returns the size of the buffer being used, otherwise returns 0.

int **NpyIter_GetNDim** (*NpyIter* *iter)

Returns the number of dimensions being iterated. If a multi-index was not requested in the iterator constructor, this value may be smaller than the number of dimensions in the original objects.

int **NpyIter_GetNOp** (*NpyIter* *iter)

Returns the number of operands in the iterator.

numpy_intp ***NpyIter_GetAxisStrideArray** (*NpyIter* *iter, int axis)

Gets the array of strides for the specified axis. Requires that the iterator be tracking a multi-index, and that buffering not be enabled.

This may be used when you want to match up operand axes in some fashion, then remove them with *NpyIter_RemoveAxis* to handle their processing manually. By calling this function before removing the axes, you can get the strides for the manual processing.

Returns NULL on error.

int **NpyIter_GetShape** (*NpyIter* *iter, *numpy_intp* *outshape)

Returns the broadcast shape of the iterator in *outshape*. This can only be called on an iterator which is tracking a multi-index.

Returns *NPY_SUCCEED* or *NPY_FAIL*.

PyArray_Descr ****NpyIter_GetDescrArray** (*NpyIter* *iter)

This gives back a pointer to the *nop* data type Descrs for the objects being iterated. The result points into *iter*, so the caller does not gain any references to the Descrs.

This pointer may be cached before the iteration loop, calling *iternext* will not change it.

PyObject ****NpyIter_GetOperandArray** (*NpyIter* *iter)

This gives back a pointer to the *nop* operand PyObjects that are being iterated. The result points into *iter*, so the caller does not gain any references to the PyObjects.

PyObject ***NpyIter_GetIterView** (*NpyIter* *iter, *numpy_intp* i)

This gives back a reference to a new ndarray view, which is a view into the *i*-th object in the array *NpyIter_GetOperandArray*, whose dimensions and strides match the internal optimized iteration pattern. A C-order iteration of this view is equivalent to the iterator's iteration order.

For example, if an iterator was created with a single array as its input, and it was possible to rearrange all its axes and then collapse it into a single strided iteration, this would return a view that is a one-dimensional array.

void **NpyIter_GetReadFlags** (*NpyIter* *iter, char *outreadflags)

Fills *nop* flags. Sets *outreadflags[i]* to 1 if *op[i]* can be read from, and to 0 if not.

void **NpyIter_GetWriteFlags** (*NpyIter* *iter, char *outwriteflags)

Fills *nop* flags. Sets *outwriteflags[i]* to 1 if *op[i]* can be written to, and to 0 if not.

int **NpyIter_CreateCompatibleStrides** (*NpyIter* *iter, *numpy_intp* itemsize, *numpy_intp* *outstrides)

Builds a set of strides which are the same as the strides of an output array created using the `NPY_ITER_ALLOCATE` flag, where NULL was passed for `op_axes`. This is for data packed contiguously, but not necessarily in C or Fortran order. This should be used together with `NpyIter_GetShape` and `NpyIter_GetNDim` with the flag `NPY_ITER_MULTI_INDEX` passed into the constructor.

A use case for this function is to match the shape and layout of the iterator and tack on one or more dimensions. For example, in order to generate a vector per input value for a numerical gradient, you pass in `ndim*itemsize` for `itemsize`, then add another dimension to the end with size `ndim` and stride `itemsize`. To do the Hessian matrix, you do the same thing but add two dimensions, or take advantage of the symmetry and pack it into 1 dimension with a particular encoding.

This function may only be called if the iterator is tracking a multi-index and if `NPY_ITER_DONT_NEGATE_STRIDES` was used to prevent an axis from being iterated in reverse order.

If an array is created with this method, simply adding ‘itemsize’ for each iteration will traverse the new array matching the iterator.

Returns `NPY_SUCCEED` or `NPY_FAIL`.

numpy_bool **NpyIter_IsFirstVisit** (*NpyIter* *iter, int iop)

Checks to see whether this is the first time the elements of the specified reduction operand which the iterator points at are being seen for the first time. The function returns a reasonable answer for reduction operands and when buffering is disabled. The answer may be incorrect for buffered non-reduction operands.

This function is intended to be used in `EXTERNAL_LOOP` mode only, and will produce some wrong answers when that mode is not enabled.

If this function returns true, the caller should also check the inner loop stride of the operand, because if that stride is 0, then only the first element of the innermost external loop is being visited for the first time.

WARNING: For performance reasons, ‘iop’ is not bounds-checked, it is not confirmed that ‘iop’ is actually a reduction operand, and it is not confirmed that `EXTERNAL_LOOP` mode is enabled. These checks are the responsibility of the caller, and should be done outside of any inner loops.

Functions for iteration

NpyIter_IterNextFunc ***NpyIter_GetIterNext** (*NpyIter* *iter, char **errmsg)

Returns a function pointer for iteration. A specialized version of the function pointer may be calculated by this function instead of being stored in the iterator structure. Thus, to get good performance, it is required that the function pointer be saved in a variable rather than retrieved for each loop iteration.

Returns NULL if there is an error. If `errmsg` is non-NULL, no Python exception is set when `NPY_FAIL` is returned. Instead, `*errmsg` is set to an error message. When `errmsg` is non-NULL, the function may be safely called without holding the Python GIL.

The typical looping construct is as follows.

```
NpyIter_IterNextFunc *iternext = NpyIter_GetIterNext(iter, NULL);
char** dataptr = NpyIter_GetDataPtrArray(iter);

do {
    /* use the addresses dataptr[0], ... dataptr[nop-1] */
} while(iternext(iter));
```

When `NPY_ITER_EXTERNAL_LOOP` is specified, the typical inner loop construct is as follows.

```

NpyIter_IterNextFunc *iternext = NpyIter_GetIterNext(iter, NULL);
char** dataptr = NpyIter_GetDataPtrArray(iter);
numpy_intp* stride = NpyIter_GetInnerStrideArray(iter);
numpy_intp* size_ptr = NpyIter_GetInnerLoopSizePtr(iter), size;
numpy_intp iop, nop = NpyIter_GetNOP(iter);

do {
    size = *size_ptr;
    while (size-->0) {
        /* use the addresses dataptr[0], ... dataptr[nop-1] */
        for (iop = 0; iop < nop; ++iop) {
            dataptr[iop] += stride[iop];
        }
    }
} while (iternext());

```

Observe that we are using the `dataptr` array inside the iterator, not copying the values to a local temporary. This is possible because when `iternext()` is called, these pointers will be overwritten with fresh values, not incrementally updated.

If a compile-time fixed buffer is being used (both flags `NPY_ITER_BUFFERED` and `NPY_ITER_EXTERNAL_LOOP`), the inner size may be used as a signal as well. The size is guaranteed to become zero when `iternext()` returns false, enabling the following loop construct. Note that if you use this construct, you should not pass `NPY_ITER_GROWINNER` as a flag, because it will cause larger sizes under some circumstances.

```

/* The constructor should have buffersize passed as this value */
#define FIXED_BUFFER_SIZE 1024

NpyIter_IterNextFunc *iternext = NpyIter_GetIterNext(iter, NULL);
char** dataptr = NpyIter_GetDataPtrArray(iter);
numpy_intp* stride = NpyIter_GetInnerStrideArray(iter);
numpy_intp* size_ptr = NpyIter_GetInnerLoopSizePtr(iter), size;
numpy_intp i, iop, nop = NpyIter_GetNOP(iter);

/* One loop with a fixed inner size */
size = *size_ptr;
while (size == FIXED_BUFFER_SIZE) {
    /*
     * This loop could be manually unrolled by a factor
     * which divides into FIXED_BUFFER_SIZE
     */
    for (i = 0; i < FIXED_BUFFER_SIZE; ++i) {
        /* use the addresses dataptr[0], ... dataptr[nop-1] */
        for (iop = 0; iop < nop; ++iop) {
            dataptr[iop] += stride[iop];
        }
    }
    iternext();
    size = *size_ptr;
}

/* Finish-up loop with variable inner size */
if (size > 0) do {
    size = *size_ptr;
    while (size-->0) {
        /* use the addresses dataptr[0], ... dataptr[nop-1] */

```

(continues on next page)

(continued from previous page)

```

    for (iop = 0; iop < nop; ++iop) {
        dataptr[iop] += stride[iop];
    }
}
} while (iternext());

```

NpyIter_GetMultiIndexFunc ***NpyIter_GetGetMultiIndex** (*NpyIter* *iter, char **errmsg)

Returns a function pointer for getting the current multi-index of the iterator. Returns NULL if the iterator is not tracking a multi-index. It is recommended that this function pointer be cached in a local variable before the iteration loop.

Returns NULL if there is an error. If errmsg is non-NULL, no Python exception is set when `NPY_FAIL` is returned. Instead, *errmsg is set to an error message. When errmsg is non-NULL, the function may be safely called without holding the Python GIL.

char ****NpyIter_GetDataPtrArray** (*NpyIter* *iter)

This gives back a pointer to the `nop` data pointers. If `NPY_ITER_EXTERNAL_LOOP` was not specified, each data pointer points to the current data item of the iterator. If no inner iteration was specified, it points to the first data item of the inner loop.

This pointer may be cached before the iteration loop, calling `iternext` will not change it. This function may be safely called without holding the Python GIL.

char ****NpyIter_GetInitialDataPtrArray** (*NpyIter* *iter)

Gets the array of data pointers directly into the arrays (never into the buffers), corresponding to iteration index 0.

These pointers are different from the pointers accepted by `NpyIter_ResetBasePointers`, because the direction along some axes may have been reversed.

This function may be safely called without holding the Python GIL.

numpy_intp ***NpyIter_GetIndexPtr** (*NpyIter* *iter)

This gives back a pointer to the index being tracked, or NULL if no index is being tracked. It is only usable if one of the flags `NPY_ITER_C_INDEX` or `NPY_ITER_F_INDEX` were specified during construction.

When the flag `NPY_ITER_EXTERNAL_LOOP` is used, the code needs to know the parameters for doing the inner loop. These functions provide that information.

numpy_intp ***NpyIter_GetInnerStrideArray** (*NpyIter* *iter)

Returns a pointer to an array of the `nop` strides, one for each iterated object, to be used by the inner loop.

This pointer may be cached before the iteration loop, calling `iternext` will not change it. This function may be safely called without holding the Python GIL.

WARNING: While the pointer may be cached, its values may change if the iterator is buffered.

numpy_intp ***NpyIter_GetInnerLoopSizePtr** (*NpyIter* *iter)

Returns a pointer to the number of iterations the inner loop should execute.

This address may be cached before the iteration loop, calling `iternext` will not change it. The value itself may change during iteration, in particular if buffering is enabled. This function may be safely called without holding the Python GIL.

void **NpyIter_GetInnerFixedStrideArray** (*NpyIter* *iter, *numpy_intp* *out_strides)

Gets an array of strides which are fixed, or will not change during the entire iteration. For strides that may change, the value `NPY_MAX_INT` is placed in the stride.

Once the iterator is prepared for iteration (after a reset if `NPY_ITER_DELAY_BUFALLOC` was used), call this to get the strides which may be used to select a fast inner loop function. For example, if the stride is 0, that means

the inner loop can always load its value into a variable once, then use the variable throughout the loop, or if the stride equals the itemsize, a contiguous version for that operand may be used.

This function may be safely called without holding the Python GIL.

Converting from previous NumPy iterators

The old iterator API includes functions like `PyArrayIter_Check`, `PyArray_Iter*` and `PyArray_ITER_*`. The multi-iterator array includes `PyArray_MultiIter*`, `PyArray_Broadcast`, and `PyArray_RemoveSmallest`. The new iterator design replaces all of this functionality with a single object and associated API. One goal of the new API is that all uses of the existing iterator should be replaceable with the new iterator without significant effort. In 1.6, the major exception to this is the neighborhood iterator, which does not have corresponding features in this iterator.

Here is a conversion table for which functions to use with the new iterator:

<i>Iterator Functions</i>	
<code>PyArray_IterNew</code>	<code>NpyIter_New</code>
<code>PyArray_IterAllButAxis</code>	<code>NpyIter_New</code> + axes parameter or Iterator flag <code>NPY_ITER_EXTERNAL_LOOP</code>
<code>PyArray_BroadcastToShape</code>	NOT SUPPORTED (Use the support for multiple operands instead.)
<code>PyArrayIter_Check</code>	Will need to add this in Python exposure
<code>PyArray_ITER_RESET</code>	<code>NpyIter_Reset</code>
<code>PyArray_ITER_NEXT</code>	Function pointer from <code>NpyIter_GetIterNext</code>
<code>PyArray_ITER_DATA</code>	<code>NpyIter_GetDataPtrArray</code>
<code>PyArray_ITER_GOTO</code>	<code>NpyIter_GotoMultiIndex</code>
<code>PyArray_ITER_GOTO1D</code>	<code>NpyIter_GotoIndex</code> or <code>NpyIter_GotoIterIndex</code>
<code>PyArray_ITER_NOTDONE</code>	Return value of <code>iternext</code> function pointer
<i>Multi-iterator Functions</i>	
<code>PyArray_MultiIterNew</code>	<code>NpyIter_MultiNew</code>
<code>PyArray_MultiIter_RESET</code>	<code>NpyIter_Reset</code>
<code>PyArray_MultiIter_NEXT</code>	Function pointer from <code>NpyIter_GetIterNext</code>
<code>PyArray_MultiIter_DATA</code>	<code>NpyIter_GetDataPtrArray</code>
<code>PyArray_MultiIter_NEXTi</code>	NOT SUPPORTED (always lock-step iteration)
<code>PyArray_MultiIter_GOTO</code>	<code>NpyIter_GotoMultiIndex</code>
<code>PyArray_MultiIter_GOTO1D</code>	<code>NpyIter_GotoIndex</code> or <code>NpyIter_GotoIterIndex</code>
<code>PyArray_MultiIter_NOTDONE</code>	Return value of <code>iternext</code> function pointer
<code>PyArray_Broadcast</code>	Handled by <code>NpyIter_MultiNew</code>
<code>PyArray_RemoveSmallest</code>	Iterator flag <code>NPY_ITER_EXTERNAL_LOOP</code>
<i>Other Functions</i>	
<code>PyArray_ConvertToCommonTy</code>	Iterator flag <code>NPY_ITER_COMMON_DTYPE</code>

2.1.6 ufunc API

Constants

`UFUNC_{THING}_{ERR}`

Deprecated, use `NPY_{THING}_{ERR}` instead

`UFUNC_FPE_DIVIDEBYZERO`

`UFUNC_FPE_OVERFLOW`

UFUNC_FPE_UNDERFLOW

UFUNC_FPE_INVALID

PyUFunc_{VALUE}

PyUFunc_One

PyUFunc_Zero

PyUFunc_MinusOne

PyUFunc_ReorderableNone

PyUFunc_None

PyUFunc_IdentityValue

Macros

NPY_LOOP_BEGIN_THREADS

Used in universal function code to only release the Python GIL if loop->obj is not true (*i.e.* this is not an OBJECT array loop). Requires use of `NPY_BEGIN_THREADS_DEF` in variable declaration area.

NPY_LOOP_END_THREADS

Used in universal function code to re-acquire the Python GIL if it was released (because loop->obj was not true).

Types

type **PyUFuncGenericFunction**

Pointers to functions that actually implement the underlying (element-by-element) function N times with the following signature:

void **loopfunc** (char **args, *numpy_intp* const *dimensions, *numpy_intp* const *steps, void *data)

Parameters

- **args** – An array of pointers to the actual data for the input and output arrays. The input arguments are given first followed by the output arguments.
- **dimensions** – A pointer to the size of the dimension over which this function is looping.
- **steps** – A pointer to the number of bytes to jump to get to the next element in this dimension for each of the input and output arguments.
- **data** – Arbitrary data (extra arguments, function names, *etc.*) that can be stored with the ufunc and will be passed in when it is called. May be NULL.

Changed in version 1.23.0: Accepts NULL *data* in addition to array of NULL values.

This is an example of a func specialized for addition of doubles returning doubles.

```
static void
double_add(char **args,
           numpy_intp const *dimensions,
           numpy_intp const *steps,
           void *extra)
{
```

(continues on next page)

(continued from previous page)

```

    npy_intp i;
    npy_intp is1 = steps[0], is2 = steps[1];
    npy_intp os = steps[2], n = dimensions[0];
    char *i1 = args[0], *i2 = args[1], *op = args[2];
    for (i = 0; i < n; i++) {
        *((double *)op) = *((double *)i1) +
                          *((double *)i2);

        i1 += is1;
        i2 += is2;
        op += os;
    }
}

```

Functions

PyObject *`PyUFunc_FromFuncAndData` (*PyUFuncGenericFunction* *func, void *const *data, const char *types, int ntypes, int nin, int nout, int identity, const char *name, const char *doc, int unused)

Create a new broadcasting universal function from required variables. Each ufunc builds around the notion of an element-by-element operation. Each ufunc object contains pointers to 1-d loops implementing the basic functionality for each supported type.

Note: The *func*, *data*, *types*, *name*, and *doc* arguments are not copied by `PyUFunc_FromFuncAndData`. The caller must ensure that the memory used by these arrays is not freed as long as the ufunc object is alive.

Parameters

- **func** – Must point to an array containing *ntypes* *PyUFuncGenericFunction* elements.
- **data** – Should be NULL or a pointer to an array of size *ntypes*. This array may contain arbitrary extra-data to be passed to the corresponding loop function in the func array, including NULL.
- **types** – Length (nin + nout) * *ntypes* array of char encoding the *numpy.dtype.num* (built-in only) that the corresponding function in the func array accepts. For instance, for a comparison ufunc with three *ntypes*, two *nin* and one *nout*, where the first function accepts *numpy.int32* and the second *numpy.int64*, with both returning *numpy.bool_*, types would be (char[]) {5, 5, 0, 7, 7, 0} since `NPY_INT32` is 5, `NPY_INT64` is 7, and `NPY_BOOL` is 0.

The bit-width names can also be used (e.g. `NPY_INT32`, `NPY_COMPLEX128`) if desired.

ufuncs.casting will be used at runtime to find the first func callable by the input/output provided.

- **ntypes** – How many different data-type-specific functions the ufunc has implemented.
- **nin** – The number of inputs to this operation.
- **nout** – The number of outputs
- **identity** – Either *PyUFunc_One*, *PyUFunc_Zero*, *PyUFunc_MinusOne*, or *PyUFunc_None*. This specifies what should be returned when an empty array is passed to the reduce method of the ufunc. The special value *PyUFunc_IdentityValue* may only be

used with the `PyUFunc_FromFuncAndDataAndSignatureAndIdentity` method, to allow an arbitrary python object to be used as the identity.

- **name** – The name for the ufunc as a NULL terminated string. Specifying a name of ‘add’ or ‘multiply’ enables a special behavior for integer-typed reductions when no dtype is given. If the input type is an integer (or boolean) data type smaller than the size of the `numpy.int_` data type, it will be internally upcast to the `numpy.int_` (or `numpy.uint`) data type.
- **doc** – Allows passing in a documentation string to be stored with the ufunc. The documentation string should not contain the name of the function or the calling signature as that will be dynamically determined from the object and available when accessing the `__doc__` attribute of the ufunc.
- **unused** – Unused and present for backwards compatibility of the C-API.

```
PyObject *PyUFunc_FromFuncAndDataAndSignature (PyUFuncGenericFunction *func, void *const *data,
                                                const char *types, int ntypes, int nin, int nout, int
                                                identity, const char *name, const char *doc, int
                                                unused, const char *signature)
```

This function is very similar to `PyUFunc_FromFuncAndData` above, but has an extra *signature* argument, to define a *generalized universal functions*. Similarly to how ufuncs are built around an element-by-element operation, gufuncs are around subarray-by-subarray operations, the *signature* defining the subarrays to operate on.

Parameters

- **signature** – The signature for the new gufunc. Setting it to NULL is equivalent to calling `PyUFunc_FromFuncAndData`. A copy of the string is made, so the passed in buffer can be freed.

```
PyObject *PyUFunc_FromFuncAndDataAndSignatureAndIdentity (PyUFuncGenericFunction *func,
                                                           void **data, char *types, int ntypes,
                                                           int nin, int nout, int identity, char
                                                           *name, char *doc, int unused, char
                                                           *signature, PyObject
                                                           *identity_value)
```

This function is very similar to `PyUFunc_FromFuncAndDataAndSignature` above, but has an extra *identity_value* argument, to define an arbitrary identity for the ufunc when *identity* is passed as `PyUFunc_IdentityValue`.

Parameters

- **identity_value** – The identity for the new gufunc. Must be passed as NULL unless the *identity* argument is `PyUFunc_IdentityValue`. Setting it to NULL is equivalent to calling `PyUFunc_FromFuncAndDataAndSignature`.

```
int PyUFunc_RegisterLoopForType (PyUFuncObject *ufunc, int usertype, PyUFuncGenericFunction function,
                                int *arg_types, void *data)
```

This function allows the user to register a 1-d loop with an already- created ufunc to be used whenever the ufunc is called with any of its input arguments as the user-defined data-type. This is needed in order to make ufuncs work with built-in data-types. The data-type must have been previously registered with the numpy system. The loop is passed in as *function*. This loop can take arbitrary data which should be passed in as *data*. The data-types the loop requires are passed in as *arg_types* which must be a pointer to memory at least as large as `ufunc->nargs`.

```
int PyUFunc_RegisterLoopForDescr (PyUFuncObject *ufunc, PyArray_Descr *usertype,
                                  PyUFuncGenericFunction function, PyArray_Descr **arg_dtypes, void
                                  *data)
```

This function behaves like `PyUFunc_RegisterLoopForType` above, except that it allows the user to register a 1-d

loop using `PyArray_Descr` objects instead of dtype type num values. This allows a 1-d loop to be registered for structured array data-types and custom data-types instead of scalar data-types.

```
int PyUFunc_ReplaceLoopBySignature (PyUFuncObject *ufunc, PyUFuncGenericFunction newfunc, int
                                     *signature, PyUFuncGenericFunction *oldfunc)
```

Replace a 1-d loop matching the given *signature* in the already-created *ufunc* with the new 1-d loop *newfunc*. Return the old 1-d loop function in *oldfunc*. Return 0 on success and -1 on failure. This function works only with built-in types (use `PyUFunc_RegisterLoopForType` for user-defined types). A signature is an array of data-type numbers indicating the inputs followed by the outputs assumed by the 1-d loop.

```
void PyUFunc_clearfperr ()
```

Clear the IEEE error flags.

Generic functions

At the core of every ufunc is a collection of type-specific functions that defines the basic functionality for each of the supported types. These functions must evaluate the underlying function $N \geq 1$ times. Extra-data may be passed in that may be used during the calculation. This feature allows some general functions to be used as these basic looping functions. The general function has all the code needed to point variables to the right place and set up a function call. The general function assumes that the actual function to call is passed in as the extra data and calls it with the correct values. All of these functions are suitable for placing directly in the array of functions stored in the functions member of the `PyUFuncObject` structure.

```
void PyUFunc_f_f_As_d_d (char **args, numpy_intp const *dimensions, numpy_intp const *steps, void *func)
```

```
void PyUFunc_d_d (char **args, numpy_intp const *dimensions, numpy_intp const *steps, void *func)
```

```
void PyUFunc_f_f (char **args, numpy_intp const *dimensions, numpy_intp const *steps, void *func)
```

```
void PyUFunc_g_g (char **args, numpy_intp const *dimensions, numpy_intp const *steps, void *func)
```

```
void PyUFunc_F_F_As_D_D (char **args, numpy_intp const *dimensions, numpy_intp const *steps, void *func)
```

```
void PyUFunc_F_F (char **args, numpy_intp const *dimensions, numpy_intp const *steps, void *func)
```

```
void PyUFunc_D_D (char **args, numpy_intp const *dimensions, numpy_intp const *steps, void *func)
```

```
void PyUFunc_G_G (char **args, numpy_intp const *dimensions, numpy_intp const *steps, void *func)
```

```
void PyUFunc_e_e (char **args, numpy_intp const *dimensions, numpy_intp const *steps, void *func)
```

```
void PyUFunc_e_e_As_f_f (char **args, numpy_intp const *dimensions, numpy_intp const *steps, void *func)
```

```
void PyUFunc_e_e_As_d_d (char **args, numpy_intp const *dimensions, numpy_intp const *steps, void *func)
```

Type specific, core 1-d functions for ufuncs where each calculation is obtained by calling a function taking one input argument and returning one output. This function is passed in *func*. The letters correspond to dtypechar's of the supported data types (e - half, f - float, d - double, g - long double, F - cfloat, D - cdouble, G - clongdouble). The argument *func* must support the same signature. The `_As_X_X` variants assume ndarray's of one data type but cast the values to use an underlying function that takes a different data type. Thus, `PyUFunc_f_f_As_d_d` uses ndarray's of data type `NPY_FLOAT` but calls out to a C-function that takes double and returns double.

```
void PyUFunc_ff_f_As_dd_d (char **args, numpy_intp const *dimensions, numpy_intp const *steps, void *func)
```

```
void PyUFunc_ff_f (char **args, numpy_intp const *dimensions, numpy_intp const *steps, void *func)
```

```
void PyUFunc_dd_d (char **args, numpy_intp const *dimensions, numpy_intp const *steps, void *func)
```

void **PyUFunc_gg_g** (char **args, *numpy_intp* const *dimensions, *numpy_intp* const *steps, void *func)

void **PyUFunc_FF_F_As_DD_D** (char **args, *numpy_intp* const *dimensions, *numpy_intp* const *steps, void *func)

void **PyUFunc_DD_D** (char **args, *numpy_intp* const *dimensions, *numpy_intp* const *steps, void *func)

void **PyUFunc_FF_F** (char **args, *numpy_intp* const *dimensions, *numpy_intp* const *steps, void *func)

void **PyUFunc_GG_G** (char **args, *numpy_intp* const *dimensions, *numpy_intp* const *steps, void *func)

void **PyUFunc_ee_e** (char **args, *numpy_intp* const *dimensions, *numpy_intp* const *steps, void *func)

void **PyUFunc_ee_e_As_ff_f** (char **args, *numpy_intp* const *dimensions, *numpy_intp* const *steps, void *func)

void **PyUFunc_ee_e_As_dd_d** (char **args, *numpy_intp* const *dimensions, *numpy_intp* const *steps, void *func)

Type specific, core 1-d functions for ufuncs where each calculation is obtained by calling a function taking two input arguments and returning one output. The underlying function to call is passed in as *func*. The letters correspond to dtypechar's of the specific data type supported by the general-purpose function. The argument *func* must support the corresponding signature. The *_As_XX_X* variants assume ndarrays of one data type but cast the values at each iteration of the loop to use the underlying function that takes a different data type.

void **PyUFunc_O_O** (char **args, *numpy_intp* const *dimensions, *numpy_intp* const *steps, void *func)

void **PyUFunc_OO_O** (char **args, *numpy_intp* const *dimensions, *numpy_intp* const *steps, void *func)

One-input, one-output, and two-input, one-output core 1-d functions for the *NPY_OBJECT* data type. These functions handle reference count issues and return early on error. The actual function to call is *func* and it must accept calls with the signature (PyObject*) (PyObject*) for *PyUFunc_O_O* or (PyObject*) (PyObject *, PyObject *) for *PyUFunc_OO_O*.

void **PyUFunc_O_O_method** (char **args, *numpy_intp* const *dimensions, *numpy_intp* const *steps, void *func)

This general purpose 1-d core function assumes that *func* is a string representing a method of the input object. For each iteration of the loop, the Python object is extracted from the array and its *func* method is called returning the result to the output array.

void **PyUFunc_OO_O_method** (char **args, *numpy_intp* const *dimensions, *numpy_intp* const *steps, void *func)

This general purpose 1-d core function assumes that *func* is a string representing a method of the input object that takes one argument. The first argument in *args* is the method whose function is called, the second argument in *args* is the argument passed to the function. The output of the function is stored in the third entry of *args*.

void **PyUFunc_On_Om** (char **args, *numpy_intp* const *dimensions, *numpy_intp* const *steps, void *func)

This is the 1-d core function used by the dynamic ufuncs created by `umath.frompyfunc(function, nin, nout)`. In this case *func* is a pointer to a *PyUFunc_PyFuncData* structure which has definition

type **PyUFunc_PyFuncData**

```
typedef struct {
    int nin;
    int nout;
    PyObject *callable;
} PyUFunc_PyFuncData;
```

At each iteration of the loop, the *nin* input objects are extracted from their object arrays and placed into an argument tuple, the Python *callable* is called with the input arguments, and the *nout* outputs are placed into their object arrays.

Importing the API

PY_UFUNC_UNIQUE_SYMBOL

NO_IMPORT_UFUNC

int **PyUFunc_ImportUFuncAPI** (void)

Ensures that the UFunc C-API is imported and usable. It returns 0 on success and -1 with an error set if NumPy couldn't be imported. While preferable to call it once at module initialization, this function is very light-weight if called multiple times.

New in version 2.0: This function mainly checks for `PyUFunc_API == NULL` so it can be manually backported if desired.

import_ufunc (void)

These are the constants and functions for accessing the ufunc C-API from extension modules in precisely the same way as the array C-API can be accessed. The `import_ufunc()` function must always be called (in the initialization subroutine of the extension module). If your extension module is in one file then that is all that is required. The other two constants are useful if your extension module makes use of multiple files. In that case, define `PY_UFUNC_UNIQUE_SYMBOL` to something unique to your code and then in source files that do not contain the module initialization function but still need access to the UFUNC API, define `PY_UFUNC_UNIQUE_SYMBOL` to the same name used previously and also define `NO_IMPORT_UFUNC`.

The C-API is actually an array of function pointers. This array is created (and pointed to by a global variable) by `import_ufunc`. The global variable is either statically defined or allowed to be seen by other files depending on the state of `PY_UFUNC_UNIQUE_SYMBOL` and `NO_IMPORT_UFUNC`.

2.1.7 Generalized universal function API

See also:

Universal functions (ufunc)

There is a general need for looping over not only functions on scalars but also over functions on vectors (or arrays). This concept is realized in NumPy by generalizing the universal functions (ufuncs). In regular ufuncs, the elementary function is limited to element-by-element operations, whereas the generalized version (gufuncs) supports “sub-array” by “sub-array” operations. The Perl vector library PDL provides a similar functionality and its terms are re-used in the following.

Each generalized ufunc has information associated with it that states what the “core” dimensionality of the inputs is, as well as the corresponding dimensionality of the outputs (the element-wise ufuncs have zero core dimensions). The list of the core dimensions for all arguments is called the “signature” of a ufunc. For example, the ufunc `numpy.add` has signature `() , () -> ()` defining two scalar inputs and one scalar output.

Another example is the function `inner1d(a, b)` with a signature of `(i) , (i) -> ()`. This applies the inner product along the last axis of each input, but keeps the remaining indices intact. For example, where `a` is of shape `(3, 5, N)` and `b` is of shape `(5, N)`, this will return an output of shape `(3, 5)`. The underlying elementary function is called `3 * 5` times. In the signature, we specify one core dimension `(i)` for each input and zero core dimensions `()` for the output, since it takes two 1-d arrays and returns a scalar. By using the same name `i`, we specify that the two corresponding dimensions should be of the same size.

The dimensions beyond the core dimensions are called “loop” dimensions. In the above example, this corresponds to `(3, 5)`.

The signature determines how the dimensions of each input/output array are split into core and loop dimensions:

1. Each dimension in the signature is matched to a dimension of the corresponding passed-in array, starting from the end of the shape tuple. These are the core dimensions, and they must be present in the arrays, or an error will be raised.
2. Core dimensions assigned to the same label in the signature (e.g. the `i` in `inner1d's (i) , (i) -> ()`) must have exactly matching sizes, no broadcasting is performed.
3. The core dimensions are removed from all inputs and the remaining dimensions are broadcast together, defining the loop dimensions.
4. The shape of each output is determined from the loop dimensions plus the output's core dimensions

Typically, the size of all core dimensions in an output will be determined by the size of a core dimension with the same label in an input array. This is not a requirement, and it is possible to define a signature where a label comes up for the first time in an output, although some precautions must be taken when calling such a function. An example would be the function `euclidean_pdist(a)`, with signature `(n, d) -> (p)`, that given an array of `n` `d`-dimensional vectors, computes all unique pairwise Euclidean distances among them. The output dimension `p` must therefore be equal to $n * (n - 1) / 2$, but by default, it is the caller's responsibility to pass in an output array of the right size. If the size of a core dimension of an output cannot be determined from a passed in input or output array, an error will be raised. This can be changed by defining a `PyUFunc_ProcessCoreDimsFunc` function and assigning it to the `process_core_dims_func` field of the `PyUFuncObject` structure. See below for more details.

Note: Prior to NumPy 1.10.0, less strict checks were in place: missing core dimensions were created by prepending 1's to the shape as necessary, core dimensions with the same label were broadcast together, and undetermined dimensions were created with size 1.

Definitions

Elementary Function

Each ufunc consists of an elementary function that performs the most basic operation on the smallest portion of array arguments (e.g. adding two numbers is the most basic operation in adding two arrays). The ufunc applies the elementary function multiple times on different parts of the arrays. The input/output of elementary functions can be vectors; e.g., the elementary function of `inner1d` takes two vectors as input.

Signature

A signature is a string describing the input/output dimensions of the elementary function of a ufunc. See section below for more details.

Core Dimension

The dimensionality of each input/output of an elementary function is defined by its core dimensions (zero core dimensions correspond to a scalar input/output). The core dimensions are mapped to the last dimensions of the input/output arrays.

Dimension Name

A dimension name represents a core dimension in the signature. Different dimensions may share a name, indicating that they are of the same size.

Dimension Index

A dimension index is an integer representing a dimension name. It enumerates the dimension names according to the order of the first occurrence of each name in the signature.

Details of signature

The signature defines “core” dimensionality of input and output variables, and thereby also defines the contraction of the dimensions. The signature is represented by a string of the following format:

- Core dimensions of each input or output array are represented by a list of dimension names in parentheses, ($i_1, \dots, i_N$); a scalar input/output is denoted by (). Instead of i_1, i_2 , etc, one can use any valid Python variable name.
- Dimension lists for different arguments are separated by ", ". Input/output arguments are separated by "->".
- If one uses the same dimension name in multiple locations, this enforces the same size of the corresponding dimensions.

The formal syntax of signatures is as follows:

```
<Signature>          ::= <Input arguments> "->" <Output arguments>
<Input arguments>    ::= <Argument list>
<Output arguments>   ::= <Argument list>
<Argument list>      ::= nil | <Argument> | <Argument> ", " <Argument list>
<Argument>           ::= "(" <Core dimension list> ")"
<Core dimension list> ::= nil | <Core dimension> |
                        <Core dimension> ", " <Core dimension list>
<Core dimension>     ::= <Dimension name> <Dimension modifier>
<Dimension name>     ::= valid Python variable name | valid integer
<Dimension modifier> ::= nil | "?"
```

Notes:

1. All quotes are for clarity.
2. Unmodified core dimensions that share the same name must have the same size. Each dimension name typically corresponds to one level of looping in the elementary function’s implementation.
3. White spaces are ignored.
4. An integer as a dimension name freezes that dimension to the value.
5. If the name is suffixed with the “?” modifier, the dimension is a core dimension only if it exists on all inputs and outputs that share it; otherwise it is ignored (and replaced by a dimension of size 1 for the elementary function).

Here are some examples of signatures:

name	signature	common usage
add	() , () -> ()	binary ufunc
sum1d	(i) -> ()	reduction
inner1d	(i) , (i) -> ()	vector-vector multiplication
matmat	(m,n) , (n,p) -> (m, p)	matrix multiplication
vecmat	(n) , (n,p) -> (p)	vector-matrix multiplication
matvec	(m,n) , (n) -> (m)	matrix-vector multiplication
matmul	(m?,n) , (n,p?) -> (m?,p?)	combination of the four above
outer_inne	(i,t) , (j,t) -> (i, j)	inner over the last dimension, outer over the second to last, and loop/broadcast over the rest.
cross1d	(3) , (3) -> (3)	cross product where the last dimension is frozen and must be 3

The last is an instance of freezing a core dimension and can be used to improve ufunc performance

C-API for implementing elementary functions

The current interface remains unchanged, and `PyUFunc_FromFuncAndData` can still be used to implement (specialized) ufuncs, consisting of scalar elementary functions.

One can use `PyUFunc_FromFuncAndDataAndSignature` to declare a more general ufunc. The argument list is the same as `PyUFunc_FromFuncAndData`, with an additional argument specifying the signature as C string.

Furthermore, the callback function is of the same type as before, `void (*foo)(char **args, intp *dimensions, intp *steps, void *func)`. When invoked, `args` is a list of length `nargs` containing the data of all input/output arguments. For a scalar elementary function, `steps` is also of length `nargs`, denoting the strides used for the arguments. `dimensions` is a pointer to a single integer defining the size of the axis to be looped over.

For a non-trivial signature, `dimensions` will also contain the sizes of the core dimensions as well, starting at the second entry. Only one size is provided for each unique dimension name and the sizes are given according to the first occurrence of a dimension name in the signature.

The first `nargs` elements of `steps` remain the same as for scalar ufuncs. The following elements contain the strides of all core dimensions for all arguments in order.

For example, consider a ufunc with signature `(i, j), (i) -> ()`. In this case, `args` will contain three pointers to the data of the input/output arrays `a`, `b`, `c`. Furthermore, `dimensions` will be `[N, I, J]` to define the size of `N` of the loop and the sizes `I` and `J` for the core dimensions `i` and `j`. Finally, `steps` will be `[a_N, b_N, c_N, a_i, a_j, b_i]`, containing all necessary strides.

Customizing core dimension size processing

The optional function of type `PyUFunc_ProcessCoreDimsFunc`, stored on the `process_core_dims_func` attribute of the ufunc, provides the author of the ufunc a “hook” into the processing of the core dimensions of the arrays that were passed to the ufunc. The two primary uses of this “hook” are:

- Check that constraints on the core dimensions required by the ufunc are satisfied (and set an exception if they are not).
- Compute output shapes for any output core dimensions that were not determined by the input arrays.

As an example of the first use, consider the generalized ufunc `minmax` with signature `(n) -> (2)` that simultaneously computes the minimum and maximum of a sequence. It should require that `n > 0`, because the minimum and maximum of a sequence with length 0 is not meaningful. In this case, the ufunc author might define the function like this:

```
int minmax_process_core_dims(PyUFuncObject *ufunc,
                             npy_intp *core_dim_sizes)
{
    npy_intp n = core_dim_sizes[0];
    if (n == 0) {
        PyErr_SetString(PyExc_ValueError,
                        "minmax requires the core dimension to "
                        "be at least 1.");
        return -1;
    }
    return 0;
}
```

In this case, the length of the array `core_dim_sizes` will be 2. The second value in the array will always be 2, so there is no need for the function to inspect it. The core dimension `n` is stored in the first element. The function sets an exception and returns -1 if it finds that `n` is 0.

The second use for the “hook” is to compute the size of output arrays when the output arrays are not provided by the caller and one or more core dimension of the output is not also an input core dimension. If the ufunc does not have a function defined on the `process_core_dims_func` attribute, an unspecified output core dimension size will result in an exception being raised. With the “hook” provided by `process_core_dims_func`, the author of the ufunc can set the output size to whatever is appropriate for the ufunc.

In the array passed to the “hook” function, core dimensions that were not determined by the input are indicated by having the value -1 in the `core_dim_sizes` array. The function can replace the -1 with whatever value is appropriate for the ufunc, based on the core dimensions that occurred in the input arrays.

Warning: The function must never change a value in `core_dim_sizes` that is not -1 on input. Changing a value that was not -1 will generally result in incorrect output from the ufunc, and could result in the Python interpreter crashing.

For example, consider the generalized ufunc `conv1d` for which the elementary function computes the “full” convolution of two one-dimensional arrays `x` and `y` with lengths `m` and `n`, respectively. The output of this convolution has length $m + n - 1$. To implement this as a generalized ufunc, the signature is set to $(m), (n) \rightarrow (p)$, and in the “hook” function, if the core dimension `p` is found to be -1, it is replaced with $m + n - 1$. If `p` is *not* -1, it must be verified that the given value equals $m + n - 1$. If it does not, the function must set an exception and return -1. For a meaningful result, the operation also requires that $m + n$ is at least 1, i.e. both inputs can’t have length 0.

Here’s how that might look in code:

```
int conv1d_process_core_dims(PyUFuncObject *ufunc,
                             npy_intp *core_dim_sizes)
{
    // core_dim_sizes will hold the core dimensions [m, n, p].
    // p will be -1 if the caller did not provide the out argument.
    npy_intp m = core_dim_sizes[0];
    npy_intp n = core_dim_sizes[1];
    npy_intp p = core_dim_sizes[2];
    npy_intp required_p = m + n - 1;

    if (m == 0 && n == 0) {
        // Disallow both inputs having length 0.
        PyErr_SetString(PyExc_ValueError,
            "conv1d: both inputs have core dimension 0; the function "
            "requires that at least one input has size greater than 0.");
        return -1;
    }
    if (p == -1) {
        // Output array was not given in the call of the ufunc.
        // Set the correct output size here.
        core_dim_sizes[2] = required_p;
        return 0;
    }
    // An output array *was* given. Validate its core dimension.
    if (p != required_p) {
        PyErr_Format(PyExc_ValueError,
            "conv1d: the core dimension p of the out parameter "
            "does not equal m + n - 1, where m and n are the "
            "core dimensions of the inputs x and y; got m=%zd "
            "and n=%zd so p must be %zd, but got p=%zd.",
            m, n, required_p, p);
        return -1;
    }
}
```

(continues on next page)

(continued from previous page)

```

    return 0;
}

```

2.1.8 NpyString API

New in version 2.0.

This API allows access to the UTF-8 string data stored in NumPy StringDType arrays. See [NEP-55](#) for more in-depth details into the design of StringDType.

Examples

Loading a String

Say we are writing a ufunc implementation for StringDType. If we are given `const char *buf` pointer to the beginning of a StringDType array entry, and a `PyArray_Descr *` pointer to the array descriptor, one can access the underlying string data like so:

```

npymath_string_allocator *allocator = NpyString_acquire_allocator(
    (PyArray_StringDTypeObject *)descr);

npymath_static_string sdata = {0, NULL};
npymath_packed_static_string *packed_string = (npymath_packed_static_string *)buf;
int is_null = 0;

is_null = NpyString_load(allocator, packed_string, &sdata);

if (is_null == -1) {
    // failed to load string, set error
    return -1;
}
else if (is_null) {
    // handle missing string
    // sdata->buf is NULL
    // sdata->size is 0
}
else {
    // sdata->buf is a pointer to the beginning of a string
    // sdata->size is the size of the string
}

NpyString_release_allocator(allocator);

```

Packing a String

This example shows how to pack a new string entry into an array:

```

char *str = "Hello world";
size_t size = 11;
npymath_packed_static_string *packed_string = (npymath_packed_static_string *)buf;

npymath_string_allocator *allocator = NpyString_acquire_allocator(
    (PyArray_StringDTypeObject *)descr);

// copy contents of str into packed_string

```

(continues on next page)

(continued from previous page)

```

if (NpyString_pack(allocator, packed_string, str, size) == -1) {
    // string packing failed, set error
    return -1;
}

// packed_string contains a copy of "Hello world"

NpyString_release_allocator(allocator);

```

Types

type `npypacked_static_string`

An opaque struct that represents “packed” encoded strings. Individual entries in array buffers are instances of this struct. Direct access to the data in the struct is undefined and future version of the library may change the packed representation of strings.

type `npystatic_string`

An unpacked string allowing access to the UTF-8 string data.

```

typedef struct npy_unpacked_static_string {
    size_t size;
    const char *buf;
} npy_static_string;

```

`size_t size`

The size of the string, in bytes.

`const char *buf`

The string buffer. Holds UTF-8-encoded bytes. Does not currently end in a null string but we may decide to add null termination in the future, so do not rely on the presence or absence of null-termination.

Note that this is a `const` buffer. If you want to alter an entry in an array, you should create a new string and pack it into the array entry.

type `npystring_allocator`

An opaque pointer to an object that handles string allocation. Before using the allocator, you must acquire the allocator lock and release the lock after you are done interacting with strings managed by the allocator.

type `PyArray_StringDTypeObject`

The C struct backing instances of `StringDType` in Python. Attributes store the settings the object was created with, an instance of `npystring_allocator` that manages string allocations for arrays associated with the `DType` instance, and several attributes caching information about the missing string object that is commonly needed in cast and ufunc loop implementations.

```

typedef struct {
    PyArray_Descr base;
    PyObject *na_object;
    char coerce;
    char has_nan_na;
    char has_string_na;
    char array_owned;
    npy_static_string default_string;
    npy_static_string na_name;
    npystring_allocator *allocator;
} PyArray_StringDTypeObject;

```

PyArray_Descr **base**

The base object. Use this member to access fields common to all descriptor objects.

PyObject ***na_object**

A reference to the object representing the null value. If there is no null value (the default) this will be NULL.

char **coerce**

1 if string coercion is enabled, 0 otherwise.

char **has_nan_na**

1 if the missing string object (if any) is NaN-like, 0 otherwise.

char **has_string_na**

1 if the missing string object (if any) is a string, 0 otherwise.

char **array_owned**

1 if an array owns the StringDType instance, 0 otherwise.

numpy_static_string **default_string**

The default string to use in operations. If the missing string object is a string, this will contain the string data for the missing string.

numpy_static_string **na_name**

The name of the missing string object, if any. An empty string otherwise.

numpy_string_allocator **allocator**

The allocator instance associated with the array that owns this descriptor instance. The allocator should only be directly accessed after acquiring the `allocator_lock` and the lock should be released immediately after the allocator is no longer needed

Functions

numpy_string_allocator ***NpyString_acquire_allocator** (const *PyArray_StringDTypeObject* *descr)

Acquire the mutex locking the allocator attached to `descr`. `NpyString_release_allocator` must be called on the allocator returned by this function exactly once. Note that functions requiring the GIL should not be called while the allocator mutex is held, as doing so may cause deadlocks.

void **NpyString_acquire_allocators** (size_t n_descriptors, *PyArray_Descr* *const descrs[],
numpy_string_allocator *allocators[])

Simultaneously acquire the mutexes locking the allocators attached to multiple descriptors. Writes a pointer to the associated allocator in the `allocators` array for each StringDType descriptor in the array. If any of the descriptors are not StringDType instances, write NULL to the `allocators` array for that entry.

`n_descriptors` is the number of descriptors in the `descrs` array that should be examined. Any descriptor after `n_descriptors` elements is ignored. A buffer overflow will happen if the `descrs` array does not contain `n_descriptors` elements.

If pointers to the same descriptor are passed multiple times, only acquires the allocator mutex once but sets identical allocator pointers appropriately. The allocator mutexes must be released after this function returns, see `NpyString_release_allocators`.

Note that functions requiring the GIL should not be called while the allocator mutex is held, as doing so may cause deadlocks.

void **NpyString_release_allocator** (*numpy_string_allocator* *allocator)

Release the mutex locking an allocator. This must be called exactly once after acquiring the allocator mutex and all operations requiring the allocator are done.

If you need to release multiple allocators, see `NpyString_release_allocators`, which can correctly handle releasing the allocator once when given several references to the same allocator.

void **NpyString_release_allocators** (size_t length, *numpy_string_allocator* *allocators[])

Release the mutexes locking N allocators. length is the length of the allocators array. NULL entries are ignored.

If pointers to the same allocator are passed multiple times, only releases the allocator mutex once.

int **NpyString_load** (*numpy_string_allocator* *allocator, const *numpy_packed_static_string* *packed_string, *numpy_static_string* *unpacked_string)

Extract the packed contents of packed_string into unpacked_string.

The unpacked_string is a read-only view onto the packed_string data and should not be used to modify the string data. If packed_string is the null string, sets unpacked_string.buf to the NULL pointer. Returns -1 if unpacking the string fails, returns 1 if packed_string is the null string, and returns 0 otherwise.

A useful pattern is to define a stack-allocated numpy_static_string instance initialized to {0, NULL} and pass a pointer to the stack-allocated unpacked string to this function. This function can be used to simultaneously unpack a string and determine if it is a null string.

int **NpyString_pack_null** (*numpy_string_allocator* *allocator, *numpy_packed_static_string* *packed_string)

Pack the null string into packed_string. Returns 0 on success and -1 on failure.

int **NpyString_pack** (*numpy_string_allocator* *allocator, *numpy_packed_static_string* *packed_string, const char *buf, size_t size)

Copy and pack the first size entries of the buffer pointed to by buf into the packed_string. Returns 0 on success and -1 on failure.

2.1.9 NumPy core math library

This library contains most math-related C99 functionality, which can be used on platforms where C99 is not well supported. The core math functions have the same API as the C99 ones, except for the `numpy_*` prefix.

The available functions are defined in `<numpy/numpy_math.h>` - please refer to this header when in doubt.

Note: An effort is underway to make `npymath` smaller (since C99 compatibility of compilers has improved over time) and more easily vendorable or usable as a header-only dependency. That will avoid problems with shipping a static library built with a compiler which may not match the compiler used by a downstream package or end user. See [gh-20880](#) for details.

Floating point classification

NPY_NAN

This macro is defined to a NaN (Not a Number), and is guaranteed to have the signbit unset ('positive' NaN). The corresponding single and extension precision macro are available with the suffix F and L.

NPY_INFINITY

This macro is defined to a positive inf. The corresponding single and extension precision macro are available with the suffix F and L.

NPY_PZERO

This macro is defined to positive zero. The corresponding single and extension precision macro are available with the suffix F and L.

NPY_NZERO

This macro is defined to negative zero (that is with the sign bit set). The corresponding single and extension precision macro are available with the suffix F and L.

numpy_isnan(x)

This is an alias for C99 isnan: works for single, double and extended precision, and return a non 0 value if x is a NaN.

numpy_isfinite(x)

This is an alias for C99 isfinite: works for single, double and extended precision, and return a non 0 value if x is neither a NaN nor an infinity.

numpy_isinf(x)

This is an alias for C99 isinf: works for single, double and extended precision, and return a non 0 value if x is infinite (positive and negative).

numpy_signbit(x)

This is an alias for C99 signbit: works for single, double and extended precision, and return a non 0 value if x has the signbit set (that is the number is negative).

numpy_copysign(x, y)

This is an alias for C99 copysign: return x with the same sign as y. Works for any value, including inf and nan. Single and extended precisions are available with suffix f and l.

Useful math constants

The following math constants are available in `numpy.math.h`. Single and extended precision are also available by adding the `f` and `l` suffixes respectively.

NPY_E

Base of natural logarithm (e)

NPY_LOG2E

Logarithm to base 2 of the Euler constant ($\frac{\ln(e)}{\ln(2)}$)

NPY_LOG10E

Logarithm to base 10 of the Euler constant ($\frac{\ln(e)}{\ln(10)}$)

NPY_LOGE2

Natural logarithm of 2 ($\ln(2)$)

NPY_LOGE10

Natural logarithm of 10 ($\ln(10)$)

NPY_PI

Pi (π)

NPY_PI_2

Pi divided by 2 ($\frac{\pi}{2}$)

NPY_PI_4

Pi divided by 4 ($\frac{\pi}{4}$)

NPY_1_PI

Reciprocal of pi ($\frac{1}{\pi}$)

NPY_2_PI

Two times the reciprocal of pi ($\frac{2}{\pi}$)

NPY_EULER**The Euler constant**

$$\lim_{n \rightarrow \infty} (\sum_{k=1}^n \frac{1}{k} - \ln n)$$

Low-level floating point manipulation

Those can be useful for precise floating point comparison.

double **numpy_nextafter** (double x, double y)

This is an alias to C99 nextafter: return next representable floating point value from x in the direction of y. Single and extended precisions are available with suffix f and l.

double **numpy_spacing** (double x)

This is a function equivalent to Fortran intrinsic. Return distance between x and next representable floating point value from x, e.g. `spacing(1) == eps`. `spacing` of nan and +/- inf return nan. Single and extended precisions are available with suffix f and l.

void **numpy_set_floatstatus_divbyzero** ()

Set the divide by zero floating point exception

void **numpy_set_floatstatus_overflow** ()

Set the overflow floating point exception

void **numpy_set_floatstatus_underflow** ()

Set the underflow floating point exception

void **numpy_set_floatstatus_invalid** ()

Set the invalid floating point exception

int **numpy_get_floatstatus** ()

Get floating point status. Returns a bitmask with following possible flags:

- NPY_FPE_DIVIDEBYZERO
- NPY_FPE_OVERFLOW
- NPY_FPE_UNDERFLOW
- NPY_FPE_INVALID

Note that `numpy_get_floatstatus_barrier` is preferable as it prevents aggressive compiler optimizations reordering the call relative to the code setting the status, which could lead to incorrect results.

int **numpy_get_floatstatus_barrier** (char*)

Get floating point status. A pointer to a local variable is passed in to prevent aggressive compiler optimizations from reordering this function call relative to the code setting the status, which could lead to incorrect results.

Returns a bitmask with following possible flags:

- NPY_FPE_DIVIDEBYZERO

- NPY_FPE_OVERFLOW
- NPY_FPE_UNDERFLOW
- NPY_FPE_INVALID

int **numpy_clear_floatstatus** ()

Clears the floating point status. Returns the previous status mask.

Note that `numpy_clear_floatstatus_barrier` is preferable as it prevents aggressive compiler optimizations reordering the call relative to the code setting the status, which could lead to incorrect results.

int **numpy_clear_floatstatus_barrier** (char*)

Clears the floating point status. A pointer to a local variable is passed in to prevent aggressive compiler optimizations from reordering this function call. Returns the previous status mask.

Support for complex numbers

C99-like complex functions have been added. Those can be used if you wish to implement portable C extensions. Since NumPy 2.0 we use C99 complex types as the underlying type:

```
typedef double _Complex npy_cdouble;
typedef float _Complex npy_cfloat;
typedef long double _Complex npy_clongdouble;
```

MSVC does not support the `_Complex` type itself, but has added support for the C99 `complex.h` header by providing its own implementation. Thus, under MSVC, the equivalent MSVC types will be used:

```
typedef _Dcomplex npy_cdouble;
typedef _Fcomplex npy_cfloat;
typedef _Lcomplex npy_clongdouble;
```

Because MSVC still does not support C99 syntax for initializing a complex number, you need to restrict to C90-compatible syntax, e.g.:

```
/* a = 1 + 2i */
numpy_complex a = numpy_cpack(1, 2);
numpy_complex b;

b = numpy_log(a);
```

A few utilities have also been added in `numpy/numpy_math.h`, in order to retrieve or set the real or the imaginary part of a complex number:

```
numpy_cdouble c;
numpy_csetreal(&c, 1.0);
numpy_csetimag(&c, 0.0);
printf("%d + %di\n", numpy_creal(c), numpy_cimag(c));
```

Changed in version 2.0.0: The underlying C types for all of numpy's complex types have been changed to use C99 complex types. Up until now the following was being used to represent complex types:

```
typedef struct { double real, imag; } npy_cdouble;
typedef struct { float real, imag; } npy_cfloat;
typedef struct { npy_longdouble real, imag; } npy_clongdouble;
```

Using the `struct` representation ensured that complex numbers could be used on all platforms, even the ones without support for built-in complex types. It also meant that a static library had to be shipped together with NumPy to provide a

C99 compatibility layer for downstream packages to use. In recent years however, support for native complex types has been improved immensely, with MSVC adding built-in support for the `complex.h` header in 2019.

To ease cross-version compatibility, macros that use the new set APIs have been added.

```
#define NPY_CSETREAL(z, r) npy_csetreal(z, r)
#define NPY_CSETIMAG(z, i) npy_csetimag(z, i)
```

A compatibility layer is also provided in `numpy/npymath.h`. It checks whether the macros exist, and falls back to the 1.x syntax in case they don't.

```
#include <numpy/npymath.h>

#ifndef NPY_CSETREALF
#define NPY_CSETREALF(c, r) (c)->real = (r)
#endif
#ifndef NPY_CSETIMAGF
#define NPY_CSETIMAGF(c, i) (c)->imag = (i)
#endif
```

We suggest all downstream packages that need this functionality to copy-paste the compatibility layer code into their own sources and use that, so that they can continue to support both NumPy 1.x and 2.x without issues. Note also that the `complex.h` header is included in `numpy/npymath.h`, which makes `complex` a reserved keyword.

Linking against the core math library in an extension

To use the core math library that NumPy ships as a static library in your own Python extension, you need to add the `npymath` compile and link options to your extension. The exact steps to take will depend on the build system you are using. The generic steps to take are:

1. Add the numpy include directory (= the value of `np.get_include()`) to your include directories,
2. The `npymath` static library resides in the `lib` directory right next to numpy's include directory (i.e., `pathlib.Path(np.get_include()) / '..' / 'lib'`). Add that to your library search directories,
3. Link with `libnpymath` and `libm`.

Note: Keep in mind that when you are cross compiling, you must use the `numpy` for the platform you are building for, not the native one for the build machine. Otherwise you pick up a static library built for the wrong architecture.

When you are building with [Meson](#), use:

```
# Note that this will get easier in the future, when Meson has
# support for numpy built in; most of this can then be replaced
# by `dependency('numpy')`.
incdir_numpy = run_command(py3,
    [
        '-c',
        'import os; os.chdir(".."); import numpy; print(numpy.get_include())'
    ],
    check: true
).stdout().strip()

inc_np = include_directories(incdir_numpy)

cc = meson.get_compiler('c')
```

(continues on next page)

(continued from previous page)

```
npymath_path = incdir_numpy / '..' / 'lib'
npymath_lib = cc.find_library('npymath', dirs: npymath_path)

py3.extension_module('module_name',
    ...
    include_directories: inc_np,
    dependencies: [npymath_lib],
```

Half-precision functions

The header file `<numpy/halffloat.h>` provides functions to work with IEEE 754-2008 16-bit floating point values. While this format is not typically used for numerical computations, it is useful for storing values which require floating point but do not need much precision. It can also be used as an educational tool to understand the nature of floating point round-off error.

Like for other types, NumPy includes a typedef `np_half` for the 16 bit float. Unlike for most of the other types, you cannot use this as a normal type in C, since it is a typedef for `np_uint16`. For example, 1.0 looks like 0x3c00 to C, and if you do an equality comparison between the different signed zeros, you will get `-0.0 != 0.0 (0x8000 != 0x0000)`, which is incorrect.

For these reasons, NumPy provides an API to work with `np_half` values accessible by including `<numpy/halffloat.h>` and linking to `npymath`. For functions that are not provided directly, such as the arithmetic operations, the preferred method is to convert to float or double and back again, as in the following example.

```
np_half sum(int n, np_half *array) {
    float ret = 0;
    while(n--) {
        ret += np_half_to_float(*array++);
    }
    return np_float_to_half(ret);
}
```

NPY_HALF_ZERO

This macro is defined to positive zero.

NPY_HALF_PZERO

This macro is defined to positive zero.

NPY_HALF_NZERO

This macro is defined to negative zero.

NPY_HALF_ONE

This macro is defined to 1.0.

NPY_HALF_NEGONE

This macro is defined to -1.0.

NPY_HALF_PINF

This macro is defined to +inf.

NPY_HALF_NINF

This macro is defined to -inf.

NPY_HALF_NAN

This macro is defined to a NaN value, guaranteed to have its sign bit unset.

float **numpy_half_to_float** (*numpy_half* h)

Converts a half-precision float to a single-precision float.

double **numpy_half_to_double** (*numpy_half* h)

Converts a half-precision float to a double-precision float.

numpy_half **numpy_float_to_half** (float f)

Converts a single-precision float to a half-precision float. The value is rounded to the nearest representable half, with ties going to the nearest even. If the value is too small or too big, the system's floating point underflow or overflow bit will be set.

numpy_half **numpy_double_to_half** (double d)

Converts a double-precision float to a half-precision float. The value is rounded to the nearest representable half, with ties going to the nearest even. If the value is too small or too big, the system's floating point underflow or overflow bit will be set.

int **numpy_half_eq** (*numpy_half* h1, *numpy_half* h2)

Compares two half-precision floats (h1 == h2).

int **numpy_half_ne** (*numpy_half* h1, *numpy_half* h2)

Compares two half-precision floats (h1 != h2).

int **numpy_half_le** (*numpy_half* h1, *numpy_half* h2)

Compares two half-precision floats (h1 <= h2).

int **numpy_half_lt** (*numpy_half* h1, *numpy_half* h2)

Compares two half-precision floats (h1 < h2).

int **numpy_half_ge** (*numpy_half* h1, *numpy_half* h2)

Compares two half-precision floats (h1 >= h2).

int **numpy_half_gt** (*numpy_half* h1, *numpy_half* h2)

Compares two half-precision floats (h1 > h2).

int **numpy_half_eq_nonan** (*numpy_half* h1, *numpy_half* h2)

Compares two half-precision floats that are known to not be NaN (h1 == h2). If a value is NaN, the result is undefined.

int **numpy_half_lt_nonan** (*numpy_half* h1, *numpy_half* h2)

Compares two half-precision floats that are known to not be NaN (h1 < h2). If a value is NaN, the result is undefined.

int **numpy_half_le_nonan** (*numpy_half* h1, *numpy_half* h2)

Compares two half-precision floats that are known to not be NaN (h1 <= h2). If a value is NaN, the result is undefined.

int **numpy_half_iszero** (*numpy_half* h)

Tests whether the half-precision float has a value equal to zero. This may be slightly faster than calling `numpy_half_eq(h, NPY_ZERO)`.

int **numpy_half_isnan** (*numpy_half* h)

Tests whether the half-precision float is a NaN.

int **numpy_half_isinf** (*numpy_half* h)

Tests whether the half-precision float is plus or minus Inf.

int **numpy_half_isfinite** (*numpy_half* h)

Tests whether the half-precision float is finite (not NaN or Inf).

int **numpy_half_signbit** (*numpy_half* h)

Returns 1 if h is negative, 0 otherwise.

numpy_half **numpy_half_copysign** (*numpy_half* x, *numpy_half* y)

Returns the value of x with the sign bit copied from y. Works for any value, including Inf and NaN.

numpy_half **numpy_half_spacing** (*numpy_half* h)

This is the same for half-precision float as `numpy_spacing` and `numpy_spacingf` described in the low-level floating point section.

numpy_half **numpy_half_nextafter** (*numpy_half* x, *numpy_half* y)

This is the same for half-precision float as `numpy_nextafter` and `numpy_nextafterf` described in the low-level floating point section.

numpy_uint16 **numpy_floatbits_to_halfbits** (*numpy_uint32* f)

Low-level function which converts a 32-bit single-precision float, stored as a uint32, into a 16-bit half-precision float.

numpy_uint16 **numpy_doublebits_to_halfbits** (*numpy_uint64* d)

Low-level function which converts a 64-bit double-precision float, stored as a uint64, into a 16-bit half-precision float.

numpy_uint32 **numpy_halfbits_to_floatbits** (*numpy_uint16* h)

Low-level function which converts a 16-bit half-precision float into a 32-bit single-precision float, stored as a uint32.

numpy_uint64 **numpy_halfbits_to_doublebits** (*numpy_uint16* h)

Low-level function which converts a 16-bit half-precision float into a 64-bit double-precision float, stored as a uint64.

2.1.10 Datetime API

NumPy represents dates internally using an int64 counter and a unit metadata struct. Time differences are represented similarly using an int64 and a unit metadata struct. The functions described below are available to facilitate converting between ISO 8601 date strings, NumPy datetimes, and Python datetime objects in C.

Data types

In addition to the `numpy_datetime` and `numpy_timedelta` typedefs for `numpy_int64`, NumPy defines two additional structs that represent time unit metadata and an “exploded” view of a datetime.

type **PyArray_DatetimeMetaData**

Represents datetime unit metadata.

```
typedef struct {
    NPY_DATETIMEUNIT base;
    int num;
} PyArray_DatetimeMetaData;
```

***NPY_DATETIMEUNIT* base**

The unit of the datetime.

int **num**

A multiplier for the unit.

type **numpy_datetimestruct**

An “exploded” view of a datetime value

```
typedef struct {
    npy_int64 year;
    npy_int32 month, day, hour, min, sec, us, ps, as;
} npy_datetimestruct;
```

enum **NPY_DATETIMEUNIT**

Time units supported by NumPy. The “FR” in the names of the enum variants is short for frequency.

enumerator **NPY_FR_ERROR**

Error or undetermined units.

enumerator **NPY_FR_Y**

Years

enumerator **NPY_FR_M**

Months

enumerator **NPY_FR_W**

Weeks

enumerator **NPY_FR_D**

Days

enumerator **NPY_FR_h**

Hours

enumerator **NPY_FR_m**

Minutes

enumerator **NPY_FR_s**

Seconds

enumerator **NPY_FR_ms**

Milliseconds

enumerator **NPY_FR_us**

Microseconds

enumerator **NPY_FR_ns**

Nanoseconds

enumerator **NPY_FR_ps**

Picoseconds

enumerator **NPY_FR_fs**

Femtoseconds

enumerator **NPY_FR_as**

Attoseconds

enumerator **NPY_FR_GENERIC**

Unbound units, can convert to anything

Conversion functions

int **NpyDatetime_ConvertDatetimeStructToDatetime64** (*PyArray_DatetimeMetaData* *meta, const *numpy_datetimestruct* *dts, *numpy_datetime* *out)

Converts a datetime from a datetimestruct to a datetime in the units specified by the unit metadata. The date is assumed to be valid.

If the `num` member of the metadata struct is large, there may be integer overflow in this function.

Returns 0 on success and -1 on failure.

int **NpyDatetime_ConvertDatetime64ToDatetimeStruct** (*PyArray_DatetimeMetaData* *meta, *numpy_datetime* dt, *numpy_datetimestruct* *out)

Converts a datetime with units specified by the unit metadata to an exploded datetime struct.

Returns 0 on success and -1 on failure.

int **NpyDatetime_ConvertPyDateTimeToDatetimeStruct** (*PyObject* *obj, *numpy_datetimestruct* *out, *NPY_DATETIMEUNIT* *out_bestunit, int apply_tzinfo)

Tests for and converts a Python `datetime.datetime` or `datetime.date` object into a NumPy `numpy_datetimestruct`.

`out_bestunit` gives a suggested unit based on whether the object was a `datetime.date` or `datetime.datetime` object.

If `apply_tzinfo` is 1, this function uses the `tzinfo` to convert to UTC time, otherwise it returns the struct with the local time.

Returns -1 on error, 0 on success, and 1 (with no error set) if `obj` doesn't have the needed date or datetime attributes.

int **NpyDatetime_ParseISO8601Datetime** (char const *str, *Py_ssize_t* len, *NPY_DATETIMEUNIT* unit, *NPY_CASTING* casting, *numpy_datetimestruct* *out, *NPY_DATETIMEUNIT* *out_bestunit, *numpy_bool* *out_special)

Parses (almost) standard ISO 8601 date strings. The differences are:

- The date “20100312” is parsed as the year 20100312, not as equivalent to “2010-03-12”. The ‘-’ in the dates are not optional.
- Only seconds may have a decimal point, with up to 18 digits after it (maximum attoseconds precision).
- Either a ‘T’ as in ISO 8601 or a ‘ ’ may be used to separate the date and the time. Both are treated equivalently.
- Doesn't (yet) handle the “YYYY-DDD” or “YYYY-Www” formats.
- Doesn't handle leap seconds (seconds value has 60 in these cases).
- Doesn't handle 24:00:00 as synonym for midnight (00:00:00) tomorrow
- Accepts special values “NaT” (not a time), “Today”, (current day according to local time) and “Now” (current time in UTC).

`str` must be a NULL-terminated string, and `len` must be its length.

`unit` should contain -1 if the unit is unknown, or the unit which will be used if it is.

`casting` controls how the detected unit from the string is allowed to be cast to the ‘unit’ parameter.

`out` gets filled with the parsed date-time.

`out_bestunit` gives a suggested unit based on the amount of resolution provided in the string, or -1 for NaT.

`out_special` gets set to 1 if the parsed time was 'today', 'now', empty string, or 'NaT'. For 'today', the unit recommended is 'D', for 'now', the unit recommended is 's', and for 'NaT' the unit recommended is 'Y'.

Returns 0 on success, -1 on failure.

int `NpyDatetime_GetDatetimeISO8601StrLen` (int `local`, `NPY_DATETIMEUNIT` `base`)

Returns the string length to use for converting datetime objects with the given local time and unit settings to strings. Use this when constructing strings to supply to `NpyDatetime_MakeISO8601Datetime`.

int `NpyDatetime_MakeISO8601Datetime` (`npdatetimestruct` *`dts`, char *`outstr`, `npdatetimeunit` `outlen`, int `local`, int `utc`, `NPY_DATETIMEUNIT` `base`, int `tzoffset`, `NPY_CASTING` `casting`)

Converts an `npdatetimestruct` to an (almost) ISO 8601 NULL-terminated string. If the string fits in the space exactly, it leaves out the NULL terminator and returns success.

The differences from ISO 8601 are the 'NaT' string, and the number of year digits is ≥ 4 instead of strictly 4.

If `local` is non-zero, it produces a string in local time with a +#### timezone offset. If `local` is zero and `utc` is non-zero, produce a string ending with 'Z' to denote UTC. By default, no time zone information is attached.

`base` restricts the output to that unit. Set `base` to -1 to auto-detect a base after which all the values are zero.

`tzoffset` is used if `local` is enabled, and `tzoffset` is set to a value other than -1. This is a manual override for the local time zone to use, as an offset in minutes.

`casting` controls whether data loss is allowed by truncating the data to a coarser unit. This interacts with `local`, slightly, in order to form a date unit string as a local time, the casting must be unsafe.

Returns 0 on success, -1 on failure (for example if the output string was too short).

2.1.11 C API deprecations

Background

The API exposed by NumPy for third-party extensions has grown over years of releases, and has allowed programmers to directly access NumPy functionality from C. This API can be best described as “organic”. It has emerged from multiple competing desires and from multiple points of view over the years, strongly influenced by the desire to make it easy for users to move to NumPy from Numeric and Numarray. The core API originated with Numeric in 1995 and there are patterns such as the heavy use of macros written to mimic Python’s C-API as well as account for compiler technology of the late 90’s. There is also only a small group of volunteers who have had very little time to spend on improving this API.

There is an ongoing effort to improve the API. It is important in this effort to ensure that code that compiles for NumPy 1.X continues to compile for NumPy 1.X. At the same time, certain API’s will be marked as deprecated so that future-looking code can avoid these API’s and follow better practices.

Another important role played by deprecation markings in the C API is to move towards hiding internal details of the NumPy implementation. For those needing direct, easy, access to the data of ndarrays, this will not remove this ability. Rather, there are many potential performance optimizations which require changing the implementation details, and NumPy developers have been unable to try them because of the high value of preserving ABI compatibility. By deprecating this direct access, we will in the future be able to improve NumPy’s performance in ways we cannot presently.

Deprecation mechanism NPY_NO_DEPRECATED_API

In C, there is no equivalent to the deprecation warnings that Python supports. One way to do deprecations is to flag them in the documentation and release notes, then remove or change the deprecated features in a future major version (NumPy 2.0 and beyond). Minor versions of NumPy should not have major C-API changes, however, that prevent code that worked on a previous minor release. For example, we will do our best to ensure that code that compiled and worked on NumPy 1.4 should continue to work on NumPy 1.7 (but perhaps with compiler warnings).

To use the NPY_NO_DEPRECATED_API mechanism, you need to `#define` it to the target API version of NumPy before `#including` any NumPy headers. If you want to confirm that your code is clean against 1.7, use:

```
#define NPY_NO_DEPRECATED_API NPY_1_7_API_VERSION
```

On compilers which support a `#warning` mechanism, NumPy issues a compiler warning if you do not define the symbol `NPY_NO_DEPRECATED_API`. This way, the fact that there are deprecations will be flagged for third-party developers who may not have read the release notes closely.

Note that defining `NPY_NO_DEPRECATED_API` is not sufficient to make your extension ABI compatible with a given NumPy version. See [for-downstream-package-authors](#).

2.1.12 Memory management in NumPy

The `numpy.ndarray` is a python class. It requires additional memory allocations to hold `numpy.ndarray.strides`, `numpy.ndarray.shape` and `numpy.ndarray.data` attributes. These attributes are specially allocated after creating the python object in `__new__`. The `strides` and `shape` are stored in a piece of memory allocated internally.

The `data` allocation used to store the actual array values (which could be pointers in the case of `object` arrays) can be very large, so NumPy has provided interfaces to manage its allocation and release. This document details how those interfaces work.

Historical overview

Since version 1.7.0, NumPy has exposed a set of `PyDataMem_*` functions (`PyDataMem_NEW`, `PyDataMem_FREE`, `PyDataMem_RENEW`) which are backed by `alloc`, `free`, `realloc` respectively.

Since those early days, Python also improved its memory management capabilities, and began providing various [manage-ment policies](#) beginning in version 3.4. These routines are divided into a set of domains, each domain has a `PyMemAl-locatorEx` structure of routines for memory management. Python also added a `tracemalloc` module to trace calls to the various routines. These tracking hooks were added to the NumPy `PyDataMem_*` routines.

NumPy added a small cache of allocated memory in its internal `np_malloc_cache`, `np_malloc_cache_zero`, and `np_free_cache` functions. These wrap `alloc`, `alloc-and-memset(0)` and `free` respectively, but when `np_free_cache` is called, it adds the pointer to a short list of available blocks marked by size. These blocks can be re-used by subsequent calls to `np_malloc*`, avoiding memory thrashing.

Configurable memory routines in NumPy (NEP 49)

Users may wish to override the internal data memory routines with ones of their own. Since NumPy does not use the Python domain strategy to manage data memory, it provides an alternative set of C-APIs to change memory routines. There are no Python domain-wide strategies for large chunks of object data, so those are less suited to NumPy's needs. User who wish to change the NumPy data memory management routines can use `PyDataMem_SetHandler`, which uses a `PyDataMem_Handler` structure to hold pointers to functions used to manage the data memory. The calls are still wrapped by internal routines to call `PyTraceMalloc_Track`, `PyTraceMalloc_Untrack`. Since the functions may change during the lifetime of the process, each `ndarray` carries with it the functions used at the time of its instantiation, and these will be used to reallocate or free the data memory of the instance.

type `PyDataMem_Handler`

A struct to hold function pointers used to manipulate memory

```
typedef struct {
    char name[127]; /* multiple of 64 to keep the struct aligned */
    uint8_t version; /* currently 1 */
    PyDataMemAllocator allocator;
} PyDataMem_Handler;
```

where the allocator structure is

```
/* The declaration of free differs from PyMemAllocatorEx */
typedef struct {
    void *ctx;
    void* (*malloc) (void *ctx, size_t size);
    void* (*calloc) (void *ctx, size_t nelem, size_t elsize);
    void* (*realloc) (void *ctx, void *ptr, size_t new_size);
    void (*free) (void *ctx, void *ptr, size_t size);
} PyDataMemAllocator;
```

`PyObject *PyDataMem_SetHandler (PyObject *handler)`

Set a new allocation policy. If the input value is NULL, will reset the policy to the default. Return the previous policy, or return NULL if an error has occurred. We wrap the user-provided functions so they will still call the python and numpy memory management callback hooks.

`PyObject *PyDataMem_GetHandler ()`

Return the current policy that will be used to allocate data for the next `PyArrayObject`. On failure, return NULL.

For an example of setting up and using the `PyDataMem_Handler`, see the test in `numpy/_core/tests/test_mem_policy.py`

What happens when deallocating if there is no policy set

A rare but useful technique is to allocate a buffer outside NumPy, use `PyArray_NewFromDescr` to wrap the buffer in a `ndarray`, then switch the `OWNDATA` flag to true. When the `ndarray` is released, the appropriate function from the `ndarray`'s `PyDataMem_Handler` should be called to free the buffer. But the `PyDataMem_Handler` field was never set, it will be NULL. For backward compatibility, NumPy will call `free()` to release the buffer. If `NUMPY_WARN_IF_NO_MEM_POLICY` is set to 1, a warning will be emitted. The current default is not to emit a warning, this may change in a future version of NumPy.

A better technique would be to use a `PyCapsule` as a base object:

```
/* define a PyCapsule_Destructor, using the correct deallocator for buff */
void free_wrap(void *capsule){
    void * obj = PyCapsule_GetPointer(capsule, PyCapsule_GetName(capsule));
    free(obj);
};

/* then inside the function that creates arr from buff */
...
arr = PyArray_NewFromDescr(... buf, ...);
if (arr == NULL) {
    return NULL;
}
capsule = PyCapsule_New(buf, "my_wrapped_buffer",
                        (PyCapsule_Destructor)&free_wrap);
if (PyArray_SetBaseObject(arr, capsule) == -1) {
    Py_DECREF(arr);
    return NULL;
}
...
```

Example of memory tracing with `np.lib.tracemalloc_domain`

The builtin `tracemalloc` module can be used to track allocations inside NumPy. NumPy places its CPU memory allocations into the `np.lib.tracemalloc_domain` domain. For additional information, check: <https://docs.python.org/3/library/tracemalloc.html>.

Here is an example on how to use `np.lib.tracemalloc_domain`:

```
"""
    The goal of this example is to show how to trace memory
    from an application that has NumPy and non-NumPy sections.
    We only select the sections using NumPy related calls.
"""

import tracemalloc
import numpy as np

# Flag to determine if we select NumPy domain
use_np_domain = True

nx = 300
ny = 500

# Start to trace memory
tracemalloc.start()

# Section 1
# -----

# NumPy related call
a = np.zeros((nx,ny))

# non-NumPy related call
b = [i**2 for i in range(nx*ny)]

snapshot1 = tracemalloc.take_snapshot()
```

(continues on next page)

(continued from previous page)

```

# We filter the snapshot to only select NumPy related calls
np_domain = np.lib.tracemalloc_domain
dom_filter = tracemalloc.DomainFilter(inclusive=use_np_domain,
                                     domain=np_domain)
snapshot1 = snapshot1.filter_traces([dom_filter])
top_stats1 = snapshot1.statistics('traceback')

print("===== SNAPSHOT 1 =====")
for stat in top_stats1:
    print(f"{stat.count} memory blocks: {stat.size / 1024:.1f} KiB")
    print(stat.traceback.format()[-1])

# Clear traces of memory blocks allocated by Python
# before moving to the next section.
tracemalloc.clear_traces()

# Section 2
#-----

# We are only using NumPy
c = np.sum(a*a)

snapshot2 = tracemalloc.take_snapshot()
top_stats2 = snapshot2.statistics('traceback')

print()
print("===== SNAPSHOT 2 =====")
for stat in top_stats2:
    print(f"{stat.count} memory blocks: {stat.size / 1024:.1f} KiB")
    print(stat.traceback.format()[-1])

tracemalloc.stop()

print()
print("=====")
print("\nTracing Status : ", tracemalloc.is_tracing())

try:
    print("\nTrying to Take Snapshot After Tracing is Stopped.")
    snap = tracemalloc.take_snapshot()
except Exception as e:
    print("Exception : ", e)

```

OTHER TOPICS

3.1 Array API standard compatibility

The NumPy 2.3.0 main namespace as well as the `numpy.fft` and `numpy.linalg` namespaces are compatible with the 2024.12 version of the Python array API standard.

NumPy aims to implement support for the future versions of the standard - assuming that those future versions can be upgraded to given NumPy's [backwards compatibility policy](#).

For usage guidelines for downstream libraries and end users who want to write code that will work with both NumPy and other array libraries, we refer to the documentation of the array API standard itself and to code and developer-focused documentation in SciPy and scikit-learn.

Note that in order to use standard-complaint code with older NumPy versions (< 2.0), the [array-api-compat](#) package may be useful. For testing whether NumPy-using code is only using standard-compliant features rather than anything NumPy-specific, the [array-api-strict](#) package can be used.

History

NumPy 1.22.0 was the first version to include support for the array API standard, via a separate `numpy.array_api` submodule. This module was marked as experimental (it emitted a warning on import) and removed in NumPy 2.0 because full support (2022.12 version¹) was included in the main namespace. [NEP 47](#) and [NEP 56](#) describe the motivation and scope for implementing the array API standard in NumPy.

3.1.1 Entry point

NumPy installs an [entry point](#) that can be used for discovery purposes:

```
>>> from importlib.metadata import entry_points
>>> entry_points(group='array_api', name='numpy')
[EntryPoint(name='numpy', value='numpy', group='array_api')]
```

Note that leaving out `name='numpy'` will cause a list of entry points to be returned for all array API standard compatible implementations that installed an entry point.

¹ With a few very minor exceptions, as documented in [NEP 56](#). The `sum`, `prod` and `trace` behavior adheres to the 2023.12 version instead, as do function signatures; the only known incompatibility that may remain is that the standard forbids unsafe casts for in-place operators while NumPy supports those.

3.1.2 Inspection

NumPy implements the [array API inspection utilities](#). These functions can be accessed via the `__array_namespace_info__()` function, which returns a namespace containing the inspection utilities.

<code>__array_namespace_info__()</code>	Get the array API inspection namespace for NumPy.
---	---

class `numpy.__array_namespace_info__`

Get the array API inspection namespace for NumPy.

The array API inspection namespace defines the following functions:

- `capabilities()`
- `default_device()`
- `default_dtypes()`
- `dtypes()`
- `devices()`

See https://data-apis.org/array-api/latest/API_specification/inspection.html for more details.

Methods

<code>capabilities()</code>	Return a dictionary of array API library capabilities.
<code>default_device()</code>	The default device used for new NumPy arrays.
<code>default_dtypes(*[, device])</code>	The default data types used for new NumPy arrays.
<code>devices()</code>	The devices supported by NumPy.
<code>dtypes(*[, device, kind])</code>	The array API data types supported by NumPy.

method

`__array_namespace_info__.capabilities()`

Return a dictionary of array API library capabilities.

The resulting dictionary has the following keys:

- **“boolean indexing”**: boolean indicating whether an array library supports boolean indexing. Always `True` for NumPy.
- **“data-dependent shapes”**: boolean indicating whether an array library supports data-dependent output shapes. Always `True` for NumPy.

See https://data-apis.org/array-api/latest/API_specification/generated/array_api.info.capabilities.html for more details.

Returns

capabilities

[dict] A dictionary of array API library capabilities.

See also:

```

__array_namespace_info__.default_device
__array_namespace_info__.default_dtypes
__array_namespace_info__.dtypes
__array_namespace_info__.devices

```

Examples

```

>>> info = np.__array_namespace_info__()
>>> info.capabilities()
{'boolean indexing': True,
 'data-dependent shapes': True,
 'max dimensions': 64}

```

method

`__array_namespace_info__.default_device()`

The default device used for new NumPy arrays.

For NumPy, this always returns 'cpu'.

Returns

device

[str] The default device used for new NumPy arrays.

See also:

```

__array_namespace_info__.capabilities
__array_namespace_info__.default_dtypes
__array_namespace_info__.dtypes
__array_namespace_info__.devices

```

Examples

```

>>> info = np.__array_namespace_info__()
>>> info.default_device()
'cpu'

```

method

`__array_namespace_info__.default_dtypes(*, device=None)`

The default data types used for new NumPy arrays.

For NumPy, this always returns the following dictionary:

- “real floating”: `numpy.float64`
- “complex floating”: `numpy.complex128`
- “integral”: `numpy.intp`
- “indexing”: `numpy.intp`

Parameters

device

[str, optional] The device to get the default data types for. For NumPy, only 'cpu' is allowed.

Returns**dtypes**

[dict] A dictionary describing the default data types used for new NumPy arrays.

See also:

[`\_\_array\_namespace\_info\_\_.capabilities`](#)
[`\_\_array\_namespace\_info\_\_.default\_device`](#)
[`\_\_array\_namespace\_info\_\_.dtypes`](#)
[`\_\_array\_namespace\_info\_\_.devices`](#)

Examples

```
>>> info = np.__array_namespace_info__()  
>>> info.default_dtypes()  
{'real floating': numpy.float64,  
 'complex floating': numpy.complex128,  
 'integral': numpy.int64,  
 'indexing': numpy.int64}
```

method

`__array_namespace_info__.devices()`

The devices supported by NumPy.

For NumPy, this always returns ('cpu',).

Returns**devices**

[list of str] The devices supported by NumPy.

See also:

[`\_\_array\_namespace\_info\_\_.capabilities`](#)
[`\_\_array\_namespace\_info\_\_.default\_device`](#)
[`\_\_array\_namespace\_info\_\_.default\_dtypes`](#)
[`\_\_array\_namespace\_info\_\_.dtypes`](#)

Examples

```
>>> info = np.__array_namespace_info__()  
>>> info.devices()  
( 'cpu', )
```

method

`__array_namespace_info__.dtypes(*, device=None, kind=None)`

The array API data types supported by NumPy.

Note that this function only returns data types that are defined by the array API.

Parameters**device**

[str, optional] The device to get the data types for. For NumPy, only 'cpu' is allowed.

kind

[str or tuple of str, optional] The kind of data types to return. If `None`, all data types are returned. If a string, only data types of that kind are returned. If a tuple, a dictionary containing the union of the given kinds is returned. The following kinds are supported:

- `'bool'`: boolean data types (i.e., `bool`).
- `'signed integer'`: signed integer data types (i.e., `int8`, `int16`, `int32`, `int64`).
- `'unsigned integer'`: unsigned integer data types (i.e., `uint8`, `uint16`, `uint32`, `uint64`).
- `'integral'`: integer data types. Shorthand for `('signed integer', 'unsigned integer')`.
- `'real floating'`: real-valued floating-point data types (i.e., `float32`, `float64`).
- `'complex floating'`: complex floating-point data types (i.e., `complex64`, `complex128`).
- `'numeric'`: numeric data types. Shorthand for `('integral', 'real floating', 'complex floating')`.

Returns**dtypes**

[dict] A dictionary mapping the names of data types to the corresponding NumPy data types.

See also:

[`\_\_array\_namespace\_info\_\_.capabilities`](#)
[`\_\_array\_namespace\_info\_\_.default\_device`](#)
[`\_\_array\_namespace\_info\_\_.default\_dtypes`](#)
[`\_\_array\_namespace\_info\_\_.devices`](#)

Examples

```
>>> info = np.__array_namespace_info__()
>>> info.dtypes(kind='signed integer')
{'int8': numpy.int8,
 'int16': numpy.int16,
 'int32': numpy.int32,
 'int64': numpy.int64}
```

Returns**info**

[ModuleType] The array API inspection namespace for NumPy.

Examples

```
>>> info = np.__array_namespace_info__()  
>>> info.default_dtypes()  
{'real floating': numpy.float64,  
 'complex floating': numpy.complex128,  
 'integral': numpy.int64,  
 'indexing': numpy.int64}
```

3.2 CPU/SIMD optimizations

NumPy comes with a flexible working mechanism that allows it to harness the SIMD features that CPUs own, in order to provide faster and more stable performance on all popular platforms. Currently, NumPy supports the X86, IBM/Power, ARM7 and ARM8 architectures.

The optimization process in NumPy is carried out in three layers:

- Code is *written* using the universal intrinsics which is a set of types, macros and functions that are mapped to each supported instruction-sets by using guards that will enable use of the them only when the compiler recognizes them. This allow us to generate multiple kernels for the same functionality, in which each generated kernel represents a set of instructions that related one or multiple certain CPU features. The first kernel represents the minimum (baseline) CPU features, and the other kernels represent the additional (dispatched) CPU features.
- At *compile* time, CPU build options are used to define the minimum and additional features to support, based on user choice and compiler support. The appropriate intrinsics are overlaid with the platform / architecture intrinsics, and multiple kernels are compiled.
- At *runtime import*, the CPU is probed for the set of supported CPU features. A mechanism is used to grab the pointer to the most appropriate kernel, and this will be the one called for the function.

Note: NumPy community had a deep discussion before implementing this work, please check [NEP 38 — Using SIMD optimization instructions for performance](#) for more clarification.

3.2.1 CPU Build Options

Overview

NumPy provides configuration options to optimize performance based on CPU capabilities. These options allow you to specify which CPU features to support, balancing performance, compatibility, and binary size. This document explains how to use these options effectively across various CPU architectures.

Key Configuration Options

NumPy uses several build options to control CPU optimizations:

- `cpu-baseline`: The minimum set of CPU features required to run the compiled NumPy.
 - Default: `min` (provides compatibility across a wide range of platforms)
 - If your target CPU doesn't support all specified baseline features, NumPy will fail to load with a Python runtime error
- `cpu-baseline-detect`: controls detection of CPU baseline based on compiler flags. Default value is `auto` that enables detection if `-march=` or a similar compiler flag is used. The other possible values are `enabled` and `disabled` to respectively enable or disable it unconditionally.
- `cpu-dispatch`: Additional CPU features for which optimized code paths will be generated.
 - Default: `max` (enables all available optimizations)
 - At runtime, NumPy will automatically select the fastest available code path based on your CPU's capabilities
- `disable-optimization`: Completely disables all CPU optimizations.
 - Default: `false` (optimizations are enabled)
 - When set to `true`, disables all CPU optimized code including dispatch, SIMD, and loop unrolling
 - Useful for debugging, testing, or in environments where optimization causes issues

These options are specified at build time via meson-python arguments:

```
pip install . -Csetup-args=-Dcpu-baseline="min" -Csetup-args=-Dcpu-dispatch="max"
# or through spin
spin build -- -Dcpu-baseline="min" -Dcpu-dispatch="max"
```

`cpu-baseline` and `cpu-dispatch` can be set to specific *CPU groups*, *features*, or *special options* that perform specific actions. The following sections describe these options in detail.

Common Usage Scenarios

Building for Local Use Only

When building for your machine only and not planning to distribute:

```
python -m build --wheel -Csetup-args=-Dcpu-baseline="native" -Csetup-args=-Dcpu-
↳ dispatch="none"
```

This automatically detects and uses all CPU features available on your machine.

Note: A fatal error will be raised if `native` isn't supported by the host platform.

Excluding Specific Features

You may want to exclude certain CPU features from the dispatched features:

```
# For x86-64: exclude all AVX-512 features
python -m build --wheel -Csetup-args=-Dcpu-dispatch="max -X86_V4"

# For ARM64: exclude SVE
python -m build --wheel -Csetup-args=-Dcpu-dispatch="max -SVE"
```

Note: Excluding a feature will also exclude any successor features that are implied by the excluded feature. For example, excluding X86_V4 will exclude AVX512_ICL and AVX512_SPR as well.

Targeting Older CPUs

On x86-64, by default the baseline is set to min which maps to X86_V2. This is unsuitable for older CPUs (before 2009) or old virtual machines. To address this, set the baseline to none:

```
python -m build --wheel -Csetup-args=-Dcpu-baseline="none"
```

This will create a build that is compatible with all x86 CPUs, but without any manual optimizations or SIMD code paths for the baseline. The build will rely only on dispatched code paths for optimization.

Targeting Newer CPUs

Raising the baseline improves performance for two main reasons:

1. Dispatched kernels don't cover all code paths
2. A higher baseline leads to smaller binary size as the compiler won't generate code paths for excluded dispatched features

For CPUs from 2015 and newer, setting the baseline to X86_V3 may be suitable:

```
python -m build --wheel -Csetup-args=-Dcpu-baseline="min+X86_V3"
```

Supported CPU Features By Architecture

NumPy supports optimized code paths for multiple CPU architectures. Below are the supported feature groups for each architecture. The name of the feature group can be used in the build options `cpu-baseline` and `cpu-dispatch`.

X86

Name	Implies	Includes
X86_V2		SSE SSE2 SSE3 SSSE3 SSE4_1 SSE4_2 POPCNT CX16 LAHF
X86_V3	X86_V2	AVX AVX2 FMA3 BMI BMI2 LZCNT F16C MOVBE
X86_V4	X86_V3	AVX512F AVX512CD AVX512VL AVX512BW AVX512DQ
AVX512_I	X86_V4	AVX512VBMI AVX512VBMI2 AVX512VNNI AVX512BITALG
		AVX512VPOPCNTDQ AVX512IFMA VAES GFNI VPCLMULQDQ
AVX512_S AVX512_I		AVX512FP16

These groups correspond to CPU generations:

- X86_V2: x86-64-v2 microarchitectures (CPUs since 2009)

- X86_V3: x86-64-v3 microarchitectures (CPUs since 2015)
- X86_V4: x86-64-v4 microarchitectures (AVX-512 capable CPUs)
- AVX512_ICL: Intel Ice Lake and similar CPUs
- AVX512_SPR: Intel Sapphire Rapids and newer CPUs

Note: On 32-bit x86, `cx16` is excluded from `X86_V2`.

On IBM/POWER big-endian

Name	Implies
VSX	
VSX2	VSX
VSX3	VSX VSX2
VSX4	VSX VSX2 VSX3

On IBM/POWER little-endian

Name	Implies
VSX	VSX2
VSX2	VSX
VSX3	VSX VSX2
VSX4	VSX VSX2 VSX3

On ARMv7/A32

Name	Implies
NEON	
NEON_FP16	NEON
NEON_VFPV4	NEON NEON_FP16
ASIMD	NEON NEON_FP16 NEON_VFPV4
ASIMDHP	NEON NEON_FP16 NEON_VFPV4 ASIMD
ASIMDDP	NEON NEON_FP16 NEON_VFPV4 ASIMD
ASIMDFHM	NEON NEON_FP16 NEON_VFPV4 ASIMD ASIMDHP

On ARMv8/A64

Name	Implies
NEON	NEON_FP16 NEON_VFPV4 ASIMD
NEON_FP16	NEON NEON_VFPV4 ASIMD
NEON_VFPV4	NEON NEON_FP16 ASIMD
ASIMD	NEON NEON_FP16 NEON_VFPV4
ASIMDHP	NEON NEON_FP16 NEON_VFPV4 ASIMD
ASIMDDP	NEON NEON_FP16 NEON_VFPV4 ASIMD
ASIMDFHM	NEON NEON_FP16 NEON_VFPV4 ASIMD ASIMDHP

On IBM/ZSYSTEM(S390X)

Name	Implies
VX	
VXE	VX
VXE2	VX VXE

On RISCV64

Name	Implies
RVV	

Special Options

Beyond specific feature names, you can use these special values:

NONE

Enables no features (equivalent to an empty string).

NATIVE

Enables all features supported by the host CPU.

DETECT

Detects the features enabled by the compiler. This option is appended by default to `cpu-baseline` if `-march`, `-mcpu`, `-xhost`, or `/QxHost` is set in the environment variable `CFLAGS` unless `cpu-baseline-detect` is disabled.

MIN

Enables the minimum CPU features for each architecture:

For Arch	Implies
x86 (32-bit)	X86_V2
x86-64	X86_V2
IBM/POWER (big-endian)	NONE
IBM/POWER (little-endian)	VSX VSX2
ARMv7/ARMHF	NONE
ARMv8/AArch64	NEON NEON_FP16 NEON_VFPV4 ASIMD
IBM/ZSYSTEM(S390X)	NONE
riscv64	NONE

MAX

Enables all features supported by the compiler and platform.

Operator Operators (-/+)

Remove or add specific features, useful with MAX, MIN, and NATIVE:

- Adding a feature (+) includes all implied features
- Removing a feature (-) excludes all successor features that imply the removed feature

Examples:

```
python -m build --wheel -Csetup-args=-Dcpu-dispatch="max-X86_V4"
python -m build --wheel -Csetup-args=-Dcpu-baseline="min+X86_V4"
```

Usage And Behaviors**Case Insensitivity**

CPU features and options are case-insensitive:

```
python -m build --wheel -Csetup-args=-Dcpu-dispatch="X86_v4"
```

Mixing Features across Architectures

You can mix features from different architectures:

```
python -m build --wheel -Csetup-args=-Dcpu-baseline="X86_V4 VSX4 SVE"
```

Order Independence

The order of specified features doesn't matter:

```
python -m build --wheel -Csetup-args=-Dcpu-dispatch="SVE X86_V4 x86_v3"
```

Separators

You can use spaces or commas as separators:

```
# All of these are equivalent
python -m build --wheel -Csetup-args=-Dcpu-dispatch="X86_V2 X86_V4"
python -m build --wheel -Csetup-args=-Dcpu-dispatch=X86_V2,X86_V4
```

Feature Combination

Features specified in options are automatically combined with all implied features:

```
python -m build --wheel -Csetup-args=-Dcpu-baseline=X86_V4
```

Equivalent to:

```
python -m build --wheel -Csetup-args=-Dcpu-baseline="X86_V2 X86_V3 X86_V4"
```

Baseline Overlapping

Features specified in `cpu-baseline` will be excluded from the `cpu-dispatch` features, along with their implied features, but without excluding successor features that imply them.

For instance, if you specify `cpu-baseline="X86_V4"`, it will exclude `X86_V4` and its implied features `X86_V2` and `X86_V3` from the `cpu-dispatch` features.

Compile-time Detection

Specifying features to `cpu-dispatch` or `cpu-baseline` doesn't explicitly enable them. Features are detected at compile time, and the maximum available features based on your specified options will be enabled according to toolchain and platform support.

This detection occurs by testing feature availability in the compiler through compile-time source files containing common intrinsics for the specified features. If both the compiler and assembler support the feature, it will be enabled.

For example, if you specify `cpu-dispatch="AVX512_ICL"` but your compiler doesn't support it, the feature will be excluded from the build. However, any implied features will still be enabled if they're supported.

Platform differences

Some exceptional conditions force us to link some features together when it come to certain compilers or architectures, resulting in the impossibility of building them separately.

These conditions can be divided into two parts, as follows:

Architectural compatibility

The need to align certain CPU features that are assured to be supported by successive generations of the same architecture, some cases:

- On `ppc64le` `VSX (ISA 2.06)` and `VSX2 (ISA 2.07)` both imply one another since the first generation that supports little-endian mode is `Power-8 (ISA 2.07)`
- On `AArch64` `NEON` `NEON_FP16` `NEON_VFPV4` `ASIMD` implies each other since they are part of the hardware baseline.

For example:

```
# On ARMv8/A64, specify NEON is going to enable Advanced SIMD
# and all predecessor extensions
python -m build --wheel -Csetup-args=-Dcpu-baseline=neon
# which is equivalent to
python -m build --wheel -Csetup-args=-Dcpu-baseline="neon neon_fp16 neon_vfpv4 asimd"
```

Note: Please take a deep look at [Supported CPU Features By Architecture](#), in order to determine the features that imply one another.

Build report

In most cases, the CPU build options do not produce any fatal errors that lead to hanging the build. Most of the errors that may appear in the build log serve as heavy warnings due to the lack of some expected CPU features by the compiler.

So we strongly recommend checking the final report log, to be aware of what kind of CPU features are enabled and what are not.

You can find the final report of CPU optimizations by tracing meson build log, and here is how it looks on x86_64/gcc:

```
Test features "X86_V2" : Supported
Test features "X86_V3" : Supported

Runtime Dispatch

Importing NumPy triggers a scan of the available CPU features from the set of dispatchable features. You can restrict this scan by setting the environment variable `NPY_DISABLE_CPU_FEATURES` to a comma-, tab-, or space-separated list of features to disable.

For instance, on x86_64 this will disable X86_V4:

```
NPY_DISABLE_CPU_FEATURES="X86_V4"
```

This will raise an error if parsing fails or if the feature was not enabled through the `cpu-dispatch` build option. If the feature is supported by the build but not available on the current CPU, a warning will be emitted instead.

Tracking Dispatched Functions

You can discover which CPU targets are enabled for different optimized functions using the Python function `numpy.lib.introspect.opt_func_info`.

This function offers two optional arguments for filtering results:

1. `func_name` - For refining function names
2. `signature` - For specifying data types in the signatures

For example:

```

>> func_info = numpy.lib.introspect.opt_func_info(func_name='add|abs', signature=
→'float64|complex64')
>> print(json.dumps(func_info, indent=2))
{
  "absolute": {
    "dd": {
      "current": "baseline(X86_V2)",
      "available": "baseline(X86_V2)"
    },
    "Ff": {

```

(continues on next page)

(continued from previous page)

```

    "current": "X86_V3",
    "available": "X86_V3 baseline(X86_V2) "
  },
  "Dd": {
    "current": "X86_V3",
    "available": "X86_V3 baseline(X86_V2) "
  }
},
"add": {
  "ddd": {
    "current": "X86_V3",
    "available": "X86_V3 baseline(X86_V2) "
  },
  "FFF": {
    "current": "X86_V3",
    "available": "X86_V3 baseline(X86_V2) "
  }
}
}
}

```

3.2.2 How does the CPU dispatcher work?

NumPy dispatcher is based on multi-source compiling, which means taking a certain source and compiling it multiple times with different compiler flags and also with different C definitions that affect the code paths. This enables certain instruction-sets for each compiled object depending on the required optimizations and ends with linking the returned objects together.

This mechanism should support all compilers and it doesn't require any compiler-specific extension, but at the same time it adds a few steps to normal compilation that are explained as follows.

1- Configuration

Configuring the required optimization by the user before starting to build the source files via the two command arguments as explained above:

- `--cpu-baseline`: minimal set of required optimizations.
- `--cpu-dispatch`: dispatched set of additional optimizations.

2- Discovering the environment

In this part, we check the compiler and platform architecture and cache some of the intermediary results to speed up rebuilding.

3- Validating the requested optimizations

By testing them against the compiler, and seeing what the compiler can support according to the requested optimizations.

4- Generating the main configuration header

The generated header `_cpu_dispatch.h` contains all the definitions and headers of instruction-sets for the required optimizations that have been validated during the previous step.

It also contains extra C definitions that are used for defining NumPy's Python-level module attributes `__cpu_baseline__` and `__cpu_dispatch__`.

What is in this header?

The example header was dynamically generated by gcc on an X86 machine. The compiler supports `--cpu-baseline="sse sse2 sse3"` and `--cpu-dispatch="ssse3 sse41"`, and the result is below.

```
// The header should be located at numpy/numpy/_core/src/common/_cpu_dispatch.h
/**NOTE
** C definitions prefixed with "NPY_HAVE_" represent
** the required optimizations.
**
** C definitions prefixed with 'NPY__CPU_TARGET_' are protected and
** shouldn't be used by any NumPy C sources.
**/
/***** baseline features *****/
/** SSE **/
#define NPY_HAVE_SSE 1
#include <xmmintrin.h>
/** SSE2 **/
#define NPY_HAVE_SSE2 1
#include <emmintrin.h>
/** SSE3 **/
#define NPY_HAVE_SSE3 1
#include <pmmmintrin.h>

/***** dispatch-able features *****/
#ifdef NPY__CPU_TARGET_SSSE3
/** SSSE3 **/
#define NPY_HAVE_SSSE3 1
#include <tmmmintrin.h>
#endif
#ifdef NPY__CPU_TARGET_SSE41
/** SSE41 **/
#define NPY_HAVE_SSE41 1
#include <smmmintrin.h>
#endif
```

Baseline features are the minimal set of required optimizations configured via `--cpu-baseline`. They have no preprocessor guards and they're always on, which means they can be used in any source.

Does this mean NumPy's infrastructure passes the compiler's flags of baseline features to all sources?

Definitely, yes. But the *dispatch-able sources* are treated differently.

What if the user specifies certain **baseline features** during the build but at runtime the machine doesn't support even these features? Will the compiled code be called via one of these definitions, or maybe the compiler itself auto-generated/vectorized certain piece of code based on the provided command line compiler flags?

During the loading of the NumPy module, there's a validation step which detects this behavior. It will raise a Python runtime error to inform the user. This is to prevent the CPU reaching an illegal instruction error causing a segfault.

Dispatch-able features are our dispatched set of additional optimizations that were configured via `--cpu-dispatch`. They are not activated by default and are always guarded by other C definitions prefixed with `NPY__CPU_TARGET_`. C definitions `NPY__CPU_TARGET_` are only enabled within **dispatch-able sources**.

5- Dispatch-able sources and configuration statements

Dispatch-able sources are special C files that can be compiled multiple times with different compiler flags and also with different C definitions. These affect code paths to enable certain instruction-sets for each compiled object according to “the configuration statements” that must be declared between a C comment (`/**/`) and start with a special mark `@targets` at the top of each dispatch-able source. At the same time, dispatch-able sources will be treated as normal C sources if the optimization was disabled by the command argument `--disable-optimization`.

What are configuration statements?

Configuration statements are sort of keywords combined together to determine the required optimization for the dispatch-able source.

Example:

```
/*@targets avx2 avx512f vsx2 vsx3 asimd asimdhp */
// C code
```

The keywords mainly represent the additional optimizations configured through `--cpu-dispatch`, but it can also represent other options such as:

- Target groups: pre-configured configuration statements used for managing the required optimizations from outside the dispatch-able source.
- Policies: collections of options used for changing the default behaviors or forcing the compilers to perform certain things.
- “baseline”: a unique keyword represents the minimal optimizations that configured through `--cpu-baseline`

NumPy's infrastructure handles dispatch-able sources in four steps:

- **(A) Recognition:** Just like source templates and F2PY, the dispatch-able sources requires a special extension `*.dispatch.c` to mark C dispatch-able source files, and for C++ `*.dispatch.cpp` or `*.dispatch.cxx`
NOTE: C++ not supported yet.
- **(B) Parsing and validating:** In this step, the dispatch-able sources that had been filtered by the previous step are parsed and validated by the configuration statements for each one of them one by one in order to determine the required optimizations.
- **(C) Wrapping:** This is the approach taken by NumPy's infrastructure, which has proved to be sufficiently flexible in order to compile a single source multiple times with different C definitions and flags that affect the code paths. The process is achieved by creating a temporary C source for each required optimization that related to the additional optimization, which contains the declarations of the C definitions and includes the involved source via the C directive `#include`. For more clarification take a look at the following code for AVX512F :

```

/*
 * this definition is used by NumPy utilities as suffixes for the
 * exported symbols
 */
#define NPY__CPU_TARGET_CURRENT AVX512F
/*
 * The following definitions enable
 * definitions of the dispatch-able features that are defined within the main
 * configuration header. These are definitions for the implied features.
 */
#define NPY__CPU_TARGET_SSE
#define NPY__CPU_TARGET_SSE2
#define NPY__CPU_TARGET_SSE3
#define NPY__CPU_TARGET_SSSE3
#define NPY__CPU_TARGET_SSE41
#define NPY__CPU_TARGET_POPCNT
#define NPY__CPU_TARGET_SSE42
#define NPY__CPU_TARGET_AVX
#define NPY__CPU_TARGET_F16C
#define NPY__CPU_TARGET_FMA3
#define NPY__CPU_TARGET_AVX2
#define NPY__CPU_TARGET_AVX512F
// our dispatch-able source
#include "/the/absolute/path/of/hello.dispatch.c"

```

- **(D) Dispatch-able configuration header:** The infrastructure generates a config header for each dispatch-able source, this header mainly contains two abstract C macros used for identifying the generated objects, so they can be used for runtime dispatching certain symbols from the generated objects by any C source. It is also used for forward declarations.

The generated header takes the name of the dispatch-able source after excluding the extension and replace it with .h, for example assume we have a dispatch-able source called `hello.dispatch.c` and contains the following:

```

// hello.dispatch.c
/*@targets baseline sse42 avx512f */
#include <stdio.h>
#include "numpy/utils.h" // NPY_CAT, NPY_TOSTR

#ifndef NPY__CPU_TARGET_CURRENT
    // wrapping the dispatch-able source only happens to the additional_
    ↪optimizations
    // but if the keyword 'baseline' provided within the configuration statements,
    // the infrastructure will add extra compiling for the dispatch-able source by
    // passing it as-is to the compiler without any changes.
    #define CURRENT_TARGET(X) X
    #define NPY__CPU_TARGET_CURRENT baseline // for printing only
#else
    // since we reach to this point, that's mean we're dealing with
    // the additional optimizations, so it could be SSE42 or AVX512F
    #define CURRENT_TARGET(X) NPY_CAT(NPY_CAT(X, _), NPY__CPU_TARGET_CURRENT)
#endif
// Macro 'CURRENT_TARGET' adding the current target as suffix to the exported_
    ↪symbols,
// to avoid linking duplications, NumPy already has a macro called
// 'NPY_CPU_DISPATCH_CURFX' similar to it, located at
// numpy/numpy/_core/src/common/np_cpu_dispatch.h
// NOTE: we tend to not adding suffixes to the baseline exported symbols

```

(continues on next page)

(continued from previous page)

```
void CURRENT_TARGET(simd_whoami) (const char *extra_info)
{
    printf("I'm " NPY_TOSTR(NPY_CPU_TARGET_CURRENT) " , %s\n", extra_info);
}
```

Now assume you attached **hello.dispatch.c** to the source tree, then the infrastructure should generate a temporary config header called **hello.dispatch.h** that can be reached by any source in the source tree, and it should contain the following code :

```
#ifndef NPY_CPU_DISPATCH_EXPAND_
    // To expand the macro calls in this header
    #define NPY_CPU_DISPATCH_EXPAND_(X) X
#endif
// Undefined the following macros, due to the possibility of including config_
// headers
// multiple times within the same source and since each config header represents
// different required optimizations according to the specified configuration
// statements in the dispatch-able source that derived from it.
#undef NPY_CPU_DISPATCH_BASELINE_CALL
#undef NPY_CPU_DISPATCH_CALL
// nothing strange here, just a normal preprocessor callback
// enabled only if 'baseline' specified within the configuration statements
#define NPY_CPU_DISPATCH_BASELINE_CALL(CB, ...) \
    NPY_CPU_DISPATCH_EXPAND_(CB(__VA_ARGS__))
// 'NPY_CPU_DISPATCH_CALL' is an abstract macro is used for dispatching
// the required optimizations that specified within the configuration statements.
//
// @param CHK, Expected a macro that can be used to detect CPU features
// in runtime, which takes a CPU feature name without string quotes and
// returns the testing result in a shape of boolean value.
// NumPy already has macro called "NPY_CPU_HAVE", which fits this requirement.
//
// @param CB, a callback macro that expected to be called multiple times depending
// on the required optimizations, the callback should receive the following_
// arguments:
// 1- The pending calls of @param CHK filled up with the required CPU features,
// that need to be tested first in runtime before executing call belong to
// the compiled object.
// 2- The required optimization name, same as in 'NPY_CPU_TARGET_CURRENT'
// 3- Extra arguments in the macro itself
//
// By default the callback calls are sorted depending on the highest interest
// unless the policy "$keep_sort" was in place within the configuration statements
// see "Dive into the CPU dispatcher" for more clarification.
#define NPY_CPU_DISPATCH_CALL(CHK, CB, ...) \
    NPY_CPU_DISPATCH_EXPAND_(CB((CHK(AVX512F)), AVX512F, __VA_ARGS__)) \
    NPY_CPU_DISPATCH_EXPAND_(CB((CHK(SSE) &&CHK(SSE2) &&CHK(SSE3) &&CHK(SSSE3) && \
    CHK(SSE41)), SSE41, __VA_ARGS__))
```

An example of using the config header in light of the above:

```
// NOTE: The following macros are only defined for demonstration purposes only.
// NumPy already has a collections of macros located at
// numpy/numpy/_core/src/common/np_cpu_dispatch.h, that covers all dispatching
// and declarations scenarios.
```

(continues on next page)

(continued from previous page)

```

#include "numpy/np_cpu_features.h" // NPY_CPU_HAVE
#include "numpy/np_utils.h" // NPY_CAT, NPY_EXPAND

// An example for setting a macro that calls all the exported symbols at once
// after checking if they're supported by the running machine.
#define DISPATCH_CALL_ALL(FN, ARGS) \
    NPY_CPU_DISPATCH_CALL(NPY_CPU_HAVE, DISPATCH_CALL_ALL_CB, FN, ARGS) \
    NPY_CPU_DISPATCH_BASELINE_CALL(DISPATCH_CALL_BASELINE_ALL_CB, FN, ARGS)
// The preprocessor callbacks.
// The same suffixes as we define it in the dispatch-able source.
#define DISPATCH_CALL_ALL_CB(CHECK, TARGET_NAME, FN, ARGS) \
    if (CHECK) { NPY_CAT(NPY_CAT(FN, _), TARGET_NAME) ARGS; }
#define DISPATCH_CALL_BASELINE_ALL_CB(FN, ARGS) \
    FN NPY_EXPAND(ARGS);

// An example for setting a macro that calls the exported symbols of highest
// interest optimization, after checking if they're supported by the running
↪machine.
#define DISPATCH_CALL_HIGH(FN, ARGS) \
    if (0) {} \
    NPY_CPU_DISPATCH_CALL(NPY_CPU_HAVE, DISPATCH_CALL_HIGH_CB, FN, ARGS) \
    NPY_CPU_DISPATCH_BASELINE_CALL(DISPATCH_CALL_BASELINE_HIGH_CB, FN, ARGS)
// The preprocessor callbacks
// The same suffixes as we define it in the dispatch-able source.
#define DISPATCH_CALL_HIGH_CB(CHECK, TARGET_NAME, FN, ARGS) \
    else if (CHECK) { NPY_CAT(NPY_CAT(FN, _), TARGET_NAME) ARGS; }
#define DISPATCH_CALL_BASELINE_HIGH_CB(FN, ARGS) \
    else { FN NPY_EXPAND(ARGS); }

// NumPy has a macro called 'NPY_CPU_DISPATCH_DECLARE' can be used
// for forward declarations any kind of prototypes based on
// 'NPY_CPU_DISPATCH_CALL' and 'NPY_CPU_DISPATCH_BASELINE_CALL'.
// However in this example, we just handle it manually.
void simd_whoami(const char *extra_info);
void simd_whoami_AVX512F(const char *extra_info);
void simd_whoami_SSE41(const char *extra_info);

void trigger_me(void)
{
    // bring the auto-generated config header
    // which contains config macros 'NPY_CPU_DISPATCH_CALL' and
    // 'NPY_CPU_DISPATCH_BASELINE_CALL'.
    // it is highly recommended to include the config header before executing
    // the dispatching macros in case if there's another header in the scope.
    #include "hello.dispatch.h"
    DISPATCH_CALL_ALL(simd_whoami, ("all"))
    DISPATCH_CALL_HIGH(simd_whoami, ("the highest interest"))
    // An example of including multiple config headers in the same source
    // #include "hello2.dispatch.h"
    // DISPATCH_CALL_HIGH(another_function, ("the highest interest"))
}

```

3.3 Thread Safety

NumPy supports use in a multithreaded context via the `threading` module in the standard library. Many NumPy operations release the GIL, so unlike many situations in Python, it is possible to improve parallel performance by exploiting multithreaded parallelism in Python.

The easiest performance gains happen when each worker thread owns its own array or set of array objects, with no data directly shared between threads. Because NumPy releases the GIL for many low-level operations, threads that spend most of the time in low-level code will run in parallel.

It is possible to share NumPy arrays between threads, but extreme care must be taken to avoid creating thread safety issues when mutating arrays that are shared between multiple threads. If two threads simultaneously read from and write to the same array, they will at best produce inconsistent, racey results that are not reproducible, let alone correct. It is also possible to crash the Python interpreter by, for example, resizing an array while another thread is reading from it to compute a ufunc operation.

In the future, we may add locking to `ndarray` to make writing multithreaded algorithms using NumPy arrays safer, but for now we suggest focusing on read-only access of arrays that are shared between threads, or adding your own locking if you need to mutation and multithreading.

Note that operations that *do not* release the GIL will see no performance gains from use of the `threading` module, and instead might be better served with `multiprocessing`. In particular, operations on arrays with `dtype=np.object_` do not release the GIL.

3.3.1 Context-local state

NumPy maintains some state for ufuncs context-local basis, which means each thread in a multithreaded program or task in an asyncio program has its own independent configuration of the `numpy.errstate` (see *Floating point error handling*), and of *Text formatting options*.

You can update state stored in a context variable by entering a context manager. As soon as the context manager exits, the state will be reset to its value before entering the context manager.

3.3.2 Free-threaded Python

New in version 2.1.

Starting with NumPy 2.1 and CPython 3.13, NumPy also has experimental support for python runtimes with the GIL disabled. See <https://py-free-threading.github.io> for more information about installing and using free-threaded Python, as well as information about supporting it in libraries that depend on NumPy.

Because free-threaded Python does not have a global interpreter lock to serialize access to Python objects, there are more opportunities for threads to mutate shared state and create thread safety issues. In addition to the limitations about locking of the `ndarray` object noted above, this also means that arrays with `dtype=np.object_` are not protected by the GIL, creating data races for python objects that are not possible outside free-threaded python.

3.3.3 C-API Threading Support

For developers writing C extensions that interact with NumPy, several parts of the *C-API array documentation* provide detailed information about multithreading considerations.

3.3.4 See Also

- *Multithreaded generation* - Practical example of using NumPy's random number generators in a multithreaded context with `concurrent.futures`.

3.4 Global Configuration Options

NumPy has a few import-time, compile-time, or runtime configuration options which change the global behaviour. Most of these are related to performance or for debugging purposes and will not be interesting to the vast majority of users.

3.4.1 Performance-related options

Number of threads used for linear algebra

NumPy itself is normally intentionally limited to a single thread during function calls, however it does support multiple Python threads running at the same time. Note that for performant linear algebra NumPy uses a BLAS backend such as OpenBLAS or MKL, which may use multiple threads that may be controlled by environment variables such as `OMP_NUM_THREADS` depending on what is used. One way to control the number of threads is the package `threadpoolctl`

madvise hugepage on Linux

When working with very large arrays on modern Linux kernels, you can experience a significant speedup when `transparent hugepage` is used. The current system policy for transparent hugepages can be seen by:

```
cat /sys/kernel/mm/transparent_hugepage/enabled
```

When set to `madvise` NumPy will typically use hugepages for a performance boost. This behaviour can be modified by setting the environment variable:

```
NUMPY_MADVISE_HUGEPAGE=0
```

or setting it to 1 to always enable it. When not set, the default is to use `madvise` on Kernels 4.6 and newer. These kernels presumably experience a large speedup with hugepage support. This flag is checked at import time.

SIMD feature selection

Setting `NPY_DISABLE_CPU_FEATURES` will exclude simd features at runtime. See *Runtime Dispatch*.

3.4.2 Debugging-related options

Warn if no memory allocation policy when deallocating data

Some users might pass ownership of the data pointer to the `ndarray` by setting the `OWNDATA` flag. If they do this without setting (manually) a memory allocation policy, the default will be to call `free`. If `NUMPY_WARN_IF_NO_MEM_POLICY` is set to "1", a `RuntimeWarning` will be emitted. A better alternative is to use a `PyCapsule` with a deallocator and set the `ndarray.base`.

Changed in version 1.25.2: This variable is only checked on the first import.

3.5 NumPy security

Security issues can be reported privately as described in the project README and when opening a [new issue on the issue tracker](#).

NumPy's maintainers are not security experts. However, we are conscientious about security and experts of both the NumPy codebase and how it's used. Please do notify us before creating security advisories against NumPy as we are happy to prioritize issues or help with assessing the severity of a bug. A security advisory we are not aware of beforehand can lead to a lot of work for all involved parties.

3.5.1 Important

NumPy is not designed to be exposed directly to untrusted users. A user who can freely execute NumPy (or Python) functions must be considered to have the same privileges as the process/Python interpreter.

If one can already execute Python code, there are far worse things one can do than use all available CPU cycles, or provoke a symptom of a bug in Code like use-after-free or a segfault. Therefore, while such issues may be bugs, they are not security issues.

Before reporting a security issue, please consider and describe the attack vector in detail - and in particular whether that attack vector assumes being able to freely execute NumPy functions.

3.5.2 Advice for using NumPy on untrusted data

NumPy should be generally safe to use on *data* provided by unprivileged users and read through safe API functions (e.g. loaded from a text file or `.npy` file without pickle support). Malicious *values* or *data sizes* should never lead to privilege escalation. Note that the above refers to *array data*. We do not currently consider for example `f2py` to be safe: it is typically used to compile a program that is then run. Any `f2py` invocation must thus use the same privilege as the later execution.

The following points may be useful or should be noted when working with untrusted data:

- Exhausting memory can result in an out-of-memory kill, which is a possible denial of service attack. Possible causes could be:
 - Functions reading text files, which may require much more memory than the original input file size.
 - If users can create arbitrarily shaped arrays, NumPy's broadcasting means that intermediate or result arrays can be much larger than the inputs.
- NumPy structured dtypes allow for a large amount of complexity. Fortunately, most code fails gracefully when a structured dtype is provided unexpectedly. However, code should either disallow untrusted users to provide these (e.g. via `.npy` files) or carefully check the fields included for nested structured/subarray dtypes.

- Passing on user input should generally be considered unsafe (except for the data being read). An example would be `np.dtype(user_string)` or `dtype=user_string`.
- The speed of operations can depend on values and memory order can lead to larger temporary memory use and slower execution. This means that operations may be significantly slower or use more memory compared to simple test cases.
- When reading data, consider enforcing a specific shape (e.g. one dimensional) or dtype such as `float64`, `float32`, or `int64` to reduce complexity.

When working with non-trivial untrusted data, it is advisable to sandbox the analysis to guard against potential privilege escalation. This is especially advisable if further libraries based on NumPy are used since these add additional complexity and potential security issues.

3.6 Status of `numpy.distutils` and migration advice

`numpy.distutils` was removed in NumPy 2.5.0.

3.6.1 Migration advice

There are several build systems which are good options to migrate to. Assuming you have compiled code in your package (if not, you have several good options, e.g. the build backends offered by Poetry, Hatch or PDM) and you want to be using a well-designed, modern and reliable build system, we recommend:

1. [Meson](#), and the [meson-python](#) build backend
2. [CMake](#), and the [scikit-build-core](#) build backend

If you have modest needs (only simple Cython/C extensions; no need for Fortran, BLAS/LAPACK, nested `setup.py` files, or other features of `numpy.distutils`) and have been happy with `numpy.distutils`, you can also consider switching to `setuptools`. Note that most functionality of `numpy.distutils` is unlikely to be ported to `setuptools`.

Moving to Meson

SciPy has moved to Meson and meson-python for its 1.9.0 release. During this process, remaining issues with Meson's Python support and feature parity with `numpy.distutils` were resolved. *Note: parity means a large superset (because Meson is a good general-purpose build system); only a few BLAS/LAPACK library selection niceties are missing.* SciPy uses almost all functionality that `numpy.distutils` offers, so if SciPy has successfully made a release with Meson as the build system, there should be no blockers left to migrate, and SciPy will be a good reference for other packages who are migrating. For more details about the SciPy migration, see:

- [RFC: switch to Meson as a build system](#)
- [Tracking issue for Meson support](#)

NumPy migrated to Meson for the 1.26 release.

Moving to CMake / scikit-build

The next generation of scikit-build is called `scikit-build-core`. Where the older `scikit-build` used `setuptools` underneath, the rewrite does not. Like Meson, CMake is a good general-purpose build system.

Moving to setuptools

For projects that only use `numpy.distutils` for historical reasons, and do not actually use features beyond those that `setuptools` also supports, moving to `setuptools` is likely the solution which costs the least effort. To assess that, there are the `numpy.distutils` features that are *not* present in `setuptools`:

- Nested `setup.py` files
- Fortran build support
- BLAS/LAPACK library support (OpenBLAS, MKL, ATLAS, Netlib LAPACK/BLAS, BLIS, 64-bit ILP interface, etc.)
- Support for a few other scientific libraries, like FFTW and UMFPACK
- Better MinGW support
- Per-compiler build flag customization (e.g. `-O3` and `SSE2` flags are default)
- a simple user build config system, see [site.cfg.example](#)
- SIMD intrinsics support
- Support for the NumPy-specific `.src` templating format for `.c/.h` files

The most widely used feature is nested `setup.py` files. In case a project uses only a couple of `setup.py` files, it also could make sense to simply aggregate all the content of those files into a single `setup.py` file and then move to `setuptools`. This involves dropping all `Configuration` instances, and using `Extension` instead. E.g.,:

```
from distutils.core import setup
from distutils.extension import Extension

setup(name='foobar',
      version='1.0',
      ext_modules=[
          Extension('foopkg.foo', ['foo.c']),
          Extension('barpkg.bar', ['bar.c']),
      ],
      )
```

For more details, see the [setuptools documentation](#)

3.7 NumPy and SWIG

Introduction

The Simple Wrapper and Interface Generator (or **SWIG**) is a powerful tool for generating wrapper code for interfacing to a wide variety of scripting languages. **SWIG** can parse header files, and using only the code prototypes, create an interface to the target language. But **SWIG** is not omnipotent. For example, it cannot know from the prototype:

```
double rms(double* seq, int n);
```

what exactly `seq` is. Is it a single value to be altered in-place? Is it an array, and if so what is its length? Is it input-only? Output-only? Input-output? **SWIG** cannot determine these details, and does not attempt to do so.

If we designed `rms`, we probably made it a routine that takes an input-only array of length `n` of `double` values called `seq` and returns the root mean square. The default behavior of **SWIG**, however, will be to create a wrapper function that compiles, but is nearly impossible to use from the scripting language in the way the C routine was intended.

For Python, the preferred way of handling contiguous (or technically, *strided*) blocks of homogeneous data is with NumPy, which provides full object-oriented access to multidimensional arrays of data. Therefore, the most logical Python interface for the `rms` function would be (including doc string):

```
def rms(seq):
    """
    rms: return the root mean square of a sequence
    rms(numpy.ndarray) -> double
    rms(list) -> double
    rms(tuple) -> double
    """
```

where `seq` would be a NumPy array of `double` values, and its length `n` would be extracted from `seq` internally before being passed to the C routine. Even better, since NumPy supports construction of arrays from arbitrary Python sequences, `seq` itself could be a nearly arbitrary sequence (so long as each element can be converted to a `double`) and the wrapper code would internally convert it to a NumPy array before extracting its data and length.

SWIG allows these types of conversions to be defined via a mechanism called *typemaps*. This document provides information on how to use `numpy.i`, a **SWIG** interface file that defines a series of typemaps intended to make the type of array-related conversions described above relatively simple to implement. For example, suppose that the `rms` function prototype defined above was in a header file named `rms.h`. To obtain the Python interface discussed above, your **SWIG** interface file would need the following:

```
%{
#define SWIG_FILE_WITH_INIT
#include "rms.h"
}%

#include "numpy.i"

%init %{
import_array();
}%

%apply (double* IN_ARRAY1, int DIM1) {(double* seq, int n)};
#include "rms.h"
```

Typemaps are keyed off a list of one or more function arguments, either by type or by type and name. We will refer to such lists as *signatures*. One of the many typemaps defined by `numpy.i` is used above and has the signature `(double* IN_ARRAY1, int DIM1)`. The argument names are intended to suggest that the `double*` argument is an input array of one dimension and that the `int` represents the size of that dimension. This is precisely the pattern in the `rms` prototype.

Most likely, no actual prototypes to be wrapped will have the argument names `IN_ARRAY1` and `DIM1`. We use the **SWIG** `%apply` directive to apply the typemap for one-dimensional input arrays of type `double` to the actual prototype used by `rms`. Using `numpy.i` effectively, therefore, requires knowing what typemaps are available and what they do.

A **SWIG** interface file that includes the **SWIG** directives given above will produce wrapper code that looks something like:

```

1 PyObject *_wrap_rms(PyObject *args) {
2     PyObject *resultobj = 0;
3     double *arg1 = (double *) 0 ;
4     int arg2 ;
5     double result;
6     PyArrayObject *array1 = NULL ;
7     int is_new_object1 = 0 ;
8     PyObject * obj0 = 0 ;
9
10    if (!PyArg_ParseTuple(args, (char *) "O:rms",&obj0)) SWIG_fail;
11    {
12        array1 = obj_to_array_contiguous_allow_conversion(
13            obj0, NPY_DOUBLE, &is_new_object1);
14        npy_intp size[1] = {
15            -1
16        };
17        if (!array1 || !require_dimensions(array1, 1) ||
18            !require_size(array1, size, 1)) SWIG_fail;
19        arg1 = (double*) array1->data;
20        arg2 = (int) array1->dimensions[0];
21    }
22    result = (double)rms(arg1,arg2);
23    resultobj = SWIG_From_double((double) (result));
24    {
25        if (is_new_object1 && array1) Py_DECREF(array1);
26    }
27    return resultobj;
28 fail:
29    {
30        if (is_new_object1 && array1) Py_DECREF(array1);
31    }
32    return NULL;
33 }

```

The typemaps from `numpy.i` are responsible for the following lines of code: 12–20, 25 and 30. Line 10 parses the input to the `rms` function. From the format string `"O:rms"`, we can see that the argument list is expected to be a single Python object (specified by the `O` before the colon) and whose pointer is stored in `obj0`. A number of functions, supplied by `numpy.i`, are called to make and check the (possible) conversion from a generic Python object to a NumPy array. These functions are explained in the section [Helper Functions](#), but hopefully their names are self-explanatory. At line 12 we use `obj0` to construct a NumPy array. At line 17, we check the validity of the result: that it is non-null and that it has a single dimension of arbitrary length. Once these states are verified, we extract the data buffer and length in lines 19 and 20 so that we can call the underlying C function at line 22. Line 25 performs memory management for the case where we have created a new array that is no longer needed.

This code has a significant amount of error handling. Note the `SWIG_fail` is a macro for `goto fail`, referring to the label at line 28. If the user provides the wrong number of arguments, this will be caught at line 10. If construction of the NumPy array fails or produces an array with the wrong number of dimensions, these errors are caught at line 17. And finally, if an error is detected, memory is still managed correctly at line 30.

Note that if the C function signature was in a different order:

```
double rms(int n, double* seq);
```

that `SWIG` would not match the typemap signature given above with the argument list for `rms`. Fortunately, `numpy.i` has a set of typemaps with the data pointer given last:

```
%apply (int DIM1, double* IN_ARRAY1) {(int n, double* seq)};
```

This simply has the effect of switching the definitions of `arg1` and `arg2` in lines 3 and 4 of the generated code above, and their assignments in lines 19 and 20.

Using `numpy.i`

The `numpy.i` file is currently located in the `tools/swig` sub-directory under the `numpy` installation directory. Typically, you will want to copy it to the directory where you are developing your wrappers.

A simple module that only uses a single **SWIG** interface file should include the following:

```
%{
#define SWIG_FILE_WITH_INIT
%}
#include "numpy.i"
%init %{
import_array();
%}
```

Within a compiled Python module, `import_array()` should only get called once. This could be in a C/C++ file that you have written and is linked to the module. If this is the case, then none of your interface files should `#define SWIG_FILE_WITH_INIT` or call `import_array()`. Or, this initialization call could be in a wrapper file generated by **SWIG** from an interface file that has the `%init` block as above. If this is the case, and you have more than one **SWIG** interface file, then only one interface file should `#define SWIG_FILE_WITH_INIT` and call `import_array()`.

Available typemaps

The `typemap` directives provided by `numpy.i` for arrays of different data types, say `double` and `int`, and dimensions of different types, say `int` or `long`, are identical to one another except for the C and NumPy type specifications. The `typemaps` are therefore implemented (typically behind the scenes) via a macro:

```
%numpy_typemaps(DATA_TYPE, DATA_TYPECODE, DIM_TYPE)
```

that can be invoked for appropriate `(DATA_TYPE, DATA_TYPECODE, DIM_TYPE)` triplets. For example:

```
%numpy_typemaps(double, NPY_DOUBLE, int)
%numpy_typemaps(int, NPY_INT, int)
```

The `numpy.i` interface file uses the `%numpy_typemaps` macro to implement `typemaps` for the following C data types and `int` dimension types:

- signed char
- unsigned char
- short
- unsigned short
- int
- unsigned int
- long
- unsigned long

- long long
- unsigned long long
- float
- double

In the following descriptions, we reference a generic `DATA_TYPE`, which could be any of the C data types listed above, and `DIM_TYPE` which should be one of the many types of integers.

The typemap signatures are largely differentiated on the name given to the buffer pointer. Names with `FARRAY` are for Fortran-ordered arrays, and names with `ARRAY` are for C-ordered (or 1D arrays).

Input Arrays

Input arrays are defined as arrays of data that are passed into a routine but are not altered in-place or returned to the user. The Python input array is therefore allowed to be almost any Python sequence (such as a list) that can be converted to the requested type of array. The input array signatures are

1D:

- (`DATA_TYPE IN_ARRAY1[ANY]`)
- (`DATA_TYPE* IN_ARRAY1, int DIM1`)
- (`int DIM1, DATA_TYPE* IN_ARRAY1`)

2D:

- (`DATA_TYPE IN_ARRAY2[ANY][ANY]`)
- (`DATA_TYPE* IN_ARRAY2, int DIM1, int DIM2`)
- (`int DIM1, int DIM2, DATA_TYPE* IN_ARRAY2`)
- (`DATA_TYPE* IN_FARRAY2, int DIM1, int DIM2`)
- (`int DIM1, int DIM2, DATA_TYPE* IN_FARRAY2`)

3D:

- (`DATA_TYPE IN_ARRAY3[ANY][ANY][ANY]`)
- (`DATA_TYPE* IN_ARRAY3, int DIM1, int DIM2, int DIM3`)
- (`int DIM1, int DIM2, int DIM3, DATA_TYPE* IN_ARRAY3`)
- (`DATA_TYPE* IN_FARRAY3, int DIM1, int DIM2, int DIM3`)
- (`int DIM1, int DIM2, int DIM3, DATA_TYPE* IN_FARRAY3`)

4D:

- (`DATA_TYPE IN_ARRAY4[ANY][ANY][ANY][ANY]`)
- (`DATA_TYPE* IN_ARRAY4, DIM_TYPE DIM1, DIM_TYPE DIM2, DIM_TYPE DIM3, DIM_TYPE DIM4`)
- (`DIM_TYPE DIM1, DIM_TYPE DIM2, DIM_TYPE DIM3, , DIM_TYPE DIM4, DATA_TYPE* IN_ARRAY4`)
- (`DATA_TYPE* IN_FARRAY4, DIM_TYPE DIM1, DIM_TYPE DIM2, DIM_TYPE DIM3, DIM_TYPE DIM4`)
- (`DIM_TYPE DIM1, DIM_TYPE DIM2, DIM_TYPE DIM3, DIM_TYPE DIM4, DATA_TYPE* IN_FARRAY4`)

The first signature listed, (`DATA_TYPE IN_ARRAY[ANY]`) is for one-dimensional arrays with hard-coded dimensions. Likewise, (`DATA_TYPE IN_ARRAY2[ANY][ANY]`) is for two-dimensional arrays with hard-coded dimensions, and similarly for three-dimensional.

In-Place Arrays

In-place arrays are defined as arrays that are modified in-place. The input values may or may not be used, but the values at the time the function returns are significant. The provided Python argument must therefore be a NumPy array of the required type. The in-place signatures are

1D:

- (`DATA_TYPE INPLACE_ARRAY1[ANY]`)
- (`DATA_TYPE* INPLACE_ARRAY1, int DIM1`)
- (`int DIM1, DATA_TYPE* INPLACE_ARRAY1`)

2D:

- (`DATA_TYPE INPLACE_ARRAY2[ANY][ANY]`)
- (`DATA_TYPE* INPLACE_ARRAY2, int DIM1, int DIM2`)
- (`int DIM1, int DIM2, DATA_TYPE* INPLACE_ARRAY2`)
- (`DATA_TYPE* INPLACE_FARRAY2, int DIM1, int DIM2`)
- (`int DIM1, int DIM2, DATA_TYPE* INPLACE_FARRAY2`)

3D:

- (`DATA_TYPE INPLACE_ARRAY3[ANY][ANY][ANY]`)
- (`DATA_TYPE* INPLACE_ARRAY3, int DIM1, int DIM2, int DIM3`)
- (`int DIM1, int DIM2, int DIM3, DATA_TYPE* INPLACE_ARRAY3`)
- (`DATA_TYPE* INPLACE_FARRAY3, int DIM1, int DIM2, int DIM3`)
- (`int DIM1, int DIM2, int DIM3, DATA_TYPE* INPLACE_FARRAY3`)

4D:

- (`DATA_TYPE INPLACE_ARRAY4[ANY][ANY][ANY][ANY]`)
- (`DATA_TYPE* INPLACE_ARRAY4, DIM_TYPE DIM1, DIM_TYPE DIM2, DIM_TYPE DIM3, DIM_TYPE DIM4`)
- (`DIM_TYPE DIM1, DIM_TYPE DIM2, DIM_TYPE DIM3, , DIM_TYPE DIM4, DATA_TYPE* INPLACE_ARRAY4`)
- (`DATA_TYPE* INPLACE_FARRAY4, DIM_TYPE DIM1, DIM_TYPE DIM2, DIM_TYPE DIM3, DIM_TYPE DIM4`)
- (`DIM_TYPE DIM1, DIM_TYPE DIM2, DIM_TYPE DIM3, DIM_TYPE DIM4, DATA_TYPE* INPLACE_FARRAY4`)

These typemaps now check to make sure that the `INPLACE_ARRAY` arguments use native byte ordering. If not, an exception is raised.

There is also a “flat” in-place array for situations in which you would like to modify or process each element, regardless of the number of dimensions. One example is a “quantization” function that quantizes each element of an array in-place, be it 1D, 2D or whatever. This form checks for continuity but allows either C or Fortran ordering.

ND:

- (DATA_TYPE* INPLACE_ARRAY_FLAT, DIM_TYPE DIM_FLAT)

Argout Arrays

Argout arrays are arrays that appear in the input arguments in C, but are in fact output arrays. This pattern occurs often when there is more than one output variable and the single return argument is therefore not sufficient. In Python, the conventional way to return multiple arguments is to pack them into a sequence (tuple, list, etc.) and return the sequence. This is what the argout typemaps do. If a wrapped function that uses these argout typemaps has more than one return argument, they are packed into a tuple or list, depending on the version of Python. The Python user does not pass these arrays in, they simply get returned. For the case where a dimension is specified, the python user must provide that dimension as an argument. The argout signatures are

1D:

- (DATA_TYPE ARGOUT_ARRAY1[ANY])
- (DATA_TYPE* ARGOUT_ARRAY1, int DIM1)
- (int DIM1, DATA_TYPE* ARGOUT_ARRAY1)

2D:

- (DATA_TYPE ARGOUT_ARRAY2[ANY][ANY])

3D:

- (DATA_TYPE ARGOUT_ARRAY3[ANY][ANY][ANY])

4D:

- (DATA_TYPE ARGOUT_ARRAY4[ANY][ANY][ANY][ANY])

These are typically used in situations where in C/C++, you would allocate a(n) array(s) on the heap, and call the function to fill the array(s) values. In Python, the arrays are allocated for you and returned as new array objects.

Note that we support DATA_TYPE* argout typemaps in 1D, but not 2D or 3D. This is because of a quirk with the [SWIG](#) typemap syntax and cannot be avoided. Note that for these types of 1D typemaps, the Python function will take a single argument representing DIM1.

Argout View Arrays

Argoutview arrays are for when your C code provides you with a view of its internal data and does not require any memory to be allocated by the user. This can be dangerous. There is almost no way to guarantee that the internal data from the C code will remain in existence for the entire lifetime of the NumPy array that encapsulates it. If the user destroys the object that provides the view of the data before destroying the NumPy array, then using that array may result in bad memory references or segmentation faults. Nevertheless, there are situations, working with large data sets, where you simply have no other choice.

The C code to be wrapped for argoutview arrays are characterized by pointers: pointers to the dimensions and double pointers to the data, so that these values can be passed back to the user. The argoutview typemap signatures are therefore

1D:

- (DATA_TYPE** ARGOUTVIEW_ARRAY1, DIM_TYPE* DIM1)
- (DIM_TYPE* DIM1, DATA_TYPE** ARGOUTVIEW_ARRAY1)

2D:

- (DATA_TYPE** ARGOUTVIEW_ARRAY2, DIM_TYPE* DIM1, DIM_TYPE* DIM2)
- (DIM_TYPE* DIM1, DIM_TYPE* DIM2, DATA_TYPE** ARGOUTVIEW_ARRAY2)
- (DATA_TYPE** ARGOUTVIEW_FARRAY2, DIM_TYPE* DIM1, DIM_TYPE* DIM2)
- (DIM_TYPE* DIM1, DIM_TYPE* DIM2, DATA_TYPE** ARGOUTVIEW_FARRAY2)

3D:

- (DATA_TYPE** ARGOUTVIEW_ARRAY3, DIM_TYPE* DIM1, DIM_TYPE* DIM2, DIM_TYPE* DIM3)
- (DIM_TYPE* DIM1, DIM_TYPE* DIM2, DIM_TYPE* DIM3, DATA_TYPE** ARGOUTVIEW_ARRAY3)
- (DATA_TYPE** ARGOUTVIEW_FARRAY3, DIM_TYPE* DIM1, DIM_TYPE* DIM2, DIM_TYPE* DIM3)
- (DIM_TYPE* DIM1, DIM_TYPE* DIM2, DIM_TYPE* DIM3, DATA_TYPE** ARGOUTVIEW_FARRAY3)

4D:

- (DATA_TYPE** ARGOUTVIEW_ARRAY4, DIM_TYPE* DIM1, DIM_TYPE* DIM2, DIM_TYPE* DIM3, DIM_TYPE* DIM4)
- (DIM_TYPE* DIM1, DIM_TYPE* DIM2, DIM_TYPE* DIM3, DIM_TYPE* DIM4, DATA_TYPE** ARGOUTVIEW_ARRAY4)
- (DATA_TYPE** ARGOUTVIEW_FARRAY4, DIM_TYPE* DIM1, DIM_TYPE* DIM2, DIM_TYPE* DIM3, DIM_TYPE* DIM4)
- (DIM_TYPE* DIM1, DIM_TYPE* DIM2, DIM_TYPE* DIM3, DIM_TYPE* DIM4, DATA_TYPE** ARGOUTVIEW_FARRAY4)

Note that arrays with hard-coded dimensions are not supported. These cannot follow the double pointer signatures of these typemaps.

Memory Managed Argout View Arrays

A recent addition to `numpy.i` are typemaps that permit argout arrays with views into memory that is managed.

1D:

- (DATA_TYPE** ARGOUTVIEWWM_ARRAY1, DIM_TYPE* DIM1)
- (DIM_TYPE* DIM1, DATA_TYPE** ARGOUTVIEWWM_ARRAY1)

2D:

- (DATA_TYPE** ARGOUTVIEWWM_ARRAY2, DIM_TYPE* DIM1, DIM_TYPE* DIM2)
- (DIM_TYPE* DIM1, DIM_TYPE* DIM2, DATA_TYPE** ARGOUTVIEWWM_ARRAY2)
- (DATA_TYPE** ARGOUTVIEWWM_FARRAY2, DIM_TYPE* DIM1, DIM_TYPE* DIM2)
- (DIM_TYPE* DIM1, DIM_TYPE* DIM2, DATA_TYPE** ARGOUTVIEWWM_FARRAY2)

3D:

- (DATA_TYPE** ARGOUTVIEWWM_ARRAY3, DIM_TYPE* DIM1, DIM_TYPE* DIM2, DIM_TYPE* DIM3)
- (DIM_TYPE* DIM1, DIM_TYPE* DIM2, DIM_TYPE* DIM3, DATA_TYPE** ARGOUTVIEWWM_ARRAY3)
- (DATA_TYPE** ARGOUTVIEWWM_FARRAY3, DIM_TYPE* DIM1, DIM_TYPE* DIM2, DIM_TYPE* DIM3)
- (DIM_TYPE* DIM1, DIM_TYPE* DIM2, DIM_TYPE* DIM3, DATA_TYPE** ARGOUTVIEWWM_FARRAY3)

4D:

- (DATA_TYPE** ARGOUTVIEWM_ARRAY4, DIM_TYPE* DIM1, DIM_TYPE* DIM2, DIM_TYPE* DIM3, DIM_TYPE* DIM4)
- (DIM_TYPE* DIM1, DIM_TYPE* DIM2, DIM_TYPE* DIM3, DIM_TYPE* DIM4, DATA_TYPE** ARGOUTVIEWM_ARRAY4)
- (DATA_TYPE** ARGOUTVIEWM_FARRAY4, DIM_TYPE* DIM1, DIM_TYPE* DIM2, DIM_TYPE* DIM3, DIM_TYPE* DIM4)
- (DIM_TYPE* DIM1, DIM_TYPE* DIM2, DIM_TYPE* DIM3, DIM_TYPE* DIM4, DATA_TYPE** ARGOUTVIEWM_FARRAY4)

Output Arrays

The `numpy.i` interface file does not support typemaps for output arrays, for several reasons. First, C/C++ return arguments are limited to a single value. This prevents obtaining dimension information in a general way. Second, arrays with hard-coded lengths are not permitted as return arguments. In other words:

```
double[3] newVector(double x, double y, double z);
```

is not legal C/C++ syntax. Therefore, we cannot provide typemaps of the form:

```
%typemap(out) (TYPE[ANY]);
```

If you run into a situation where a function or method is returning a pointer to an array, your best bet is to write your own version of the function to be wrapped, either with `%extend` for the case of class methods or `%ignore` and `%rename` for the case of functions.

Other Common Types: bool

Note that C++ type `bool` is not supported in the list in the [Available Typemaps](#) section. NumPy bools are a single byte, while the C++ `bool` is four bytes (at least on my system). Therefore:

```
%numpy_typemaps(bool, NPY_BOOL, int)
```

will result in typemaps that will produce code that reference improper data lengths. You can implement the following macro expansion:

```
%numpy_typemaps(bool, NPY_UINT, int)
```

to fix the data length problem, and [Input Arrays](#) will work fine, but [In-Place Arrays](#) might fail type-checking.

Other Common Types: complex

Typemap conversions for complex floating-point types is also not supported automatically. This is because Python and NumPy are written in C, which does not have native complex types. Both Python and NumPy implement their own (essentially equivalent) `struct` definitions for complex variables:

```
/* Python */
typedef struct {double real; double imag;} Py_complex;

/* NumPy */
typedef struct {float real, imag;} npy_cfloat;
typedef struct {double real, imag;} npy_cdoube;
```

We could have implemented:

```
%numpy_typemaps(Py_complex , NPY_CDOUBLE, int)
%numpy_typemaps(npy_cfloat , NPY_CFLOAT , int)
%numpy_typemaps(npy_cdouble, NPY_CDOUBLE, int)
```

which would have provided automatic type conversions for arrays of type `Py_complex`, `npy_cfloat` and `npy_cdouble`. However, it seemed unlikely that there would be any independent (non-Python, non-NumPy) application code that people would be using [SWIG](#) to generate a Python interface to, that also used these definitions for complex types. More likely, these application codes will define their own complex types, or in the case of C++, use `std::complex`. Assuming these data structures are compatible with Python and NumPy complex types, `%numpy_typemap` expansions as above (with the user's complex type substituted for the first argument) should work.

NumPy array scalars and SWIG

[SWIG](#) has sophisticated type checking for numerical types. For example, if your C/C++ routine expects an integer as input, the code generated by [SWIG](#) will check for both Python integers and Python long integers, and raise an overflow error if the provided Python integer is too big to cast down to a C integer. With the introduction of NumPy scalar arrays into your Python code, you might conceivably extract an integer from a NumPy array and attempt to pass this to a [SWIG](#)-wrapped C/C++ function that expects an `int`, but the [SWIG](#) type checking will not recognize the NumPy array scalar as an integer. (Often, this does in fact work – it depends on whether NumPy recognizes the integer type you are using as inheriting from the Python integer type on the platform you are using. Sometimes, this means that code that works on a 32-bit machine will fail on a 64-bit machine.)

If you get a Python error that looks like the following:

```
TypeError: in method 'MyClass_MyMethod', argument 2 of type 'int'
```

and the argument you are passing is an integer extracted from a NumPy array, then you have stumbled upon this problem. The solution is to modify the [SWIG](#) type conversion system to accept NumPy array scalars in addition to the standard integer types. Fortunately, this capability has been provided for you. Simply copy the file:

```
pyfragments.swg
```

to the working build directory for your project, and this problem will be fixed. It is suggested that you do this anyway, as it only increases the capabilities of your Python interface.

Why is There a Second File?

The [SWIG](#) type checking and conversion system is a complicated combination of C macros, [SWIG](#) macros, [SWIG](#) typemaps and [SWIG](#) fragments. Fragments are a way to conditionally insert code into your wrapper file if it is needed, and not insert it if not needed. If multiple typemaps require the same fragment, the fragment only gets inserted into your wrapper code once.

There is a fragment for converting a Python integer to a C `long`. There is a different fragment that converts a Python integer to a C `int`, that calls the routine defined in the `long` fragment. We can make the changes we want here by changing the definition for the `long` fragment. [SWIG](#) determines the active definition for a fragment using a “first come, first served” system. That is, we need to define the fragment for `long` conversions prior to [SWIG](#) doing it internally. [SWIG](#) allows us to do this by putting our fragment definitions in the file `pyfragments.swg`. If we were to put the new fragment definitions in `numpy.i`, they would be ignored.

Helper functions

The `numpy.i` file contains several macros and routines that it uses internally to build its typemaps. However, these functions may be useful elsewhere in your interface file. These macros and routines are implemented as fragments, which are described briefly in the previous section. If you try to use one or more of the following macros or functions, but your compiler complains that it does not recognize the symbol, then you need to force these fragments to appear in your code using:

```
%fragment("NumPy_Fragments");
```

in your SWIG interface file.

Macros

is_array(a)

Evaluates as true if `a` is non-NULL and can be cast to a `PyArrayObject*`.

array_type(a)

Evaluates to the integer data type code of `a`, assuming `a` can be cast to a `PyArrayObject*`.

array_numdims(a)

Evaluates to the integer number of dimensions of `a`, assuming `a` can be cast to a `PyArrayObject*`.

array_dimensions(a)

Evaluates to an array of type `numpy_intp` and length `array_numdims(a)`, giving the lengths of all of the dimensions of `a`, assuming `a` can be cast to a `PyArrayObject*`.

array_size(a,i)

Evaluates to the `i`-th dimension size of `a`, assuming `a` can be cast to a `PyArrayObject*`.

array_strides(a)

Evaluates to an array of type `numpy_intp` and length `array_numdims(a)`, giving the stridess of all of the dimensions of `a`, assuming `a` can be cast to a `PyArrayObject*`. A stride is the distance in bytes between an element and its immediate neighbor along the same axis.

array_stride(a,i)

Evaluates to the `i`-th stride of `a`, assuming `a` can be cast to a `PyArrayObject*`.

array_data(a)

Evaluates to a pointer of type `void*` that points to the data buffer of `a`, assuming `a` can be cast to a `PyArrayObject*`.

array_descr(a)

Returns a borrowed reference to the `dtype` property (`PyArray_Descr*`) of `a`, assuming `a` can be cast to a `PyArrayObject*`.

array_flags(a)

Returns an integer representing the flags of `a`, assuming `a` can be cast to a `PyArrayObject*`.

array_enableflags(a,f)

Sets the flag represented by `f` of `a`, assuming `a` can be cast to a `PyArrayObject*`.

array_is_contiguous(a)

Evaluates as true if `a` is a contiguous array. Equivalent to `(PyArray_ISCONTIGUOUS(a))`.

array_is_native(a)

Evaluates as true if the data buffer of `a` uses native byte order. Equivalent to `(PyArray_ISNOTSWAPPED(a))`.

array_is_fortran(a)

Evaluates as true if `a` is FORTRAN ordered.

Routines

pytype_string()

Return type: `const char*`

Arguments:

- `PyObject* py_obj`, a general Python object.

Return a string describing the type of `py_obj`.

typecode_string()

Return type: `const char*`

Arguments:

- `int typecode`, a NumPy integer typecode.

Return a string describing the type corresponding to the NumPy typecode.

type_match()

Return type: `int`

Arguments:

- `int actual_type`, the NumPy typecode of a NumPy array.
- `int desired_type`, the desired NumPy typecode.

Make sure that `actual_type` is compatible with `desired_type`. For example, this allows character and byte types, or int and long types, to match. This is now equivalent to `PyArray_EquivTypenums()`.

obj_to_array_no_conversion()

Return type: `PyArrayObject*`

Arguments:

- `PyObject* input`, a general Python object.
- `int typecode`, the desired NumPy typecode.

Cast `input` to a `PyArrayObject*` if legal, and ensure that it is of type `typecode`. If `input` cannot be cast, or the typecode is wrong, set a Python error and return `NULL`.

obj_to_array_allow_conversion()

Return type: `PyArrayObject*`

Arguments:

- `PyObject* input`, a general Python object.
- `int typecode`, the desired NumPy typecode of the resulting array.
- `int* is_new_object`, returns a value of 0 if no conversion performed, else 1.

Convert `input` to a NumPy array with the given typecode. On success, return a valid `PyArrayObject*` with the correct type. On failure, the Python error string will be set and the routine returns `NULL`.

make_contiguous()

Return type: `PyArrayObject*`

Arguments:

- `PyArrayObject* ary`, a NumPy array.
- `int* is_new_object`, returns a value of 0 if no conversion performed, else 1.
- `int min_dims`, minimum allowable dimensions.

- `int max_dims`, maximum allowable dimensions.

Check to see if `ary` is contiguous. If so, return the input pointer and flag it as not a new object. If it is not contiguous, create a new `PyArrayObject*` using the original data, flag it as a new object and return the pointer.

make_fortran()

Return type: `PyArrayObject*`

Arguments

- `PyArrayObject* ary`, a NumPy array.
- `int* is_new_object`, returns a value of 0 if no conversion performed, else 1.

Check to see if `ary` is Fortran contiguous. If so, return the input pointer and flag it as not a new object. If it is not Fortran contiguous, create a new `PyArrayObject*` using the original data, flag it as a new object and return the pointer.

obj_to_array_contiguous_allow_conversion()

Return type: `PyArrayObject*`

Arguments:

- `PyObject* input`, a general Python object.
- `int typecode`, the desired NumPy typecode of the resulting array.
- `int* is_new_object`, returns a value of 0 if no conversion performed, else 1.

Convert input to a contiguous `PyArrayObject*` of the specified type. If the input object is not a contiguous `PyArrayObject*`, a new one will be created and the new object flag will be set.

obj_to_array_fortran_allow_conversion()

Return type: `PyArrayObject*`

Arguments:

- `PyObject* input`, a general Python object.
- `int typecode`, the desired NumPy typecode of the resulting array.
- `int* is_new_object`, returns a value of 0 if no conversion performed, else 1.

Convert input to a Fortran contiguous `PyArrayObject*` of the specified type. If the input object is not a Fortran contiguous `PyArrayObject*`, a new one will be created and the new object flag will be set.

require_contiguous()

Return type: `int`

Arguments:

- `PyArrayObject* ary`, a NumPy array.

Test whether `ary` is contiguous. If so, return 1. Otherwise, set a Python error and return 0.

require_native()

Return type: `int`

Arguments:

- `PyArray_Object* ary`, a NumPy array.

Require that `ary` is not byte-swapped. If the array is not byte-swapped, return 1. Otherwise, set a Python error and return 0.

require_dimensions()

Return type: `int`

Arguments:

- `PyArrayObject*` `ary`, a NumPy array.
- `int` `exact_dimensions`, the desired number of dimensions.

Require `ary` to have a specified number of dimensions. If the array has the specified number of dimensions, return 1. Otherwise, set a Python error and return 0.

require_dimensions_n()

Return type: `int`

Arguments:

- `PyArrayObject*` `ary`, a NumPy array.
- `int*` `exact_dimensions`, an array of integers representing acceptable numbers of dimensions.
- `int` `n`, the length of `exact_dimensions`.

Require `ary` to have one of a list of specified number of dimensions. If the array has one of the specified number of dimensions, return 1. Otherwise, set the Python error string and return 0.

require_size()

Return type: `int`

Arguments:

- `PyArrayObject*` `ary`, a NumPy array.
- `numpy_int*` `size`, an array representing the desired lengths of each dimension.
- `int` `n`, the length of `size`.

Require `ary` to have a specified shape. If the array has the specified shape, return 1. Otherwise, set the Python error string and return 0.

require_fortran()

Return type: `int`

Arguments:

- `PyArrayObject*` `ary`, a NumPy array.

Require the given `PyArrayObject` to be Fortran ordered. If the `PyArrayObject` is already Fortran ordered, do nothing. Else, set the Fortran ordering flag and recompute the strides.

Beyond the provided typemaps

There are many C or C++ array/NumPy array situations not covered by a simple `%include "numpy.i"` and subsequent `%apply` directives.

A Common Example

Consider a reasonable prototype for a dot product function:

```
double dot(int len, double* vec1, double* vec2);
```

The Python interface that we want is:

```
def dot(vec1, vec2):
    """
    dot(PyObject,PyObject) -> double
    """
```

The problem here is that there is one dimension argument and two array arguments, and our typemaps are set up for dimensions that apply to a single array (in fact, **SWIG** does not provide a mechanism for associating `len` with `vec2` that takes two Python input arguments). The recommended solution is the following:

```
%apply (int DIM1, double* IN_ARRAY1) {(int len1, double* vec1),
                                       (int len2, double* vec2)}

%rename (dot) my_dot;
%exception my_dot {
    $action
    if (PyErr_Occurred()) SWIG_fail;
}
%inline %{
double my_dot(int len1, double* vec1, int len2, double* vec2) {
    if (len1 != len2) {
        PyErr_Format(PyExc_ValueError,
                     "Arrays of lengths (%d,%d) given",
                     len1, len2);
        return 0.0;
    }
    return dot(len1, vec1, vec2);
}
%}
```

If the header file that contains the prototype for `double dot()` also contains other prototypes that you want to wrap, so that you need to `%include` this header file, then you will also need a `%ignore dot;` directive, placed after the `%rename` and before the `%include` directives. Or, if the function in question is a class method, you will want to use `%extend` rather than `%inline` in addition to `%ignore`.

A note on error handling: Note that `my_dot` returns a `double` but that it can also raise a Python error. The resulting wrapper function will return a Python float representation of 0.0 when the vector lengths do not match. Since this is not `NULL`, the Python interpreter will not know to check for an error. For this reason, we add the `%exception` directive above for `my_dot` to get the behavior we want (note that `$action` is a macro that gets expanded to a valid call to `my_dot`). In general, you will probably want to write a **SWIG** macro to perform this task.

Other Situations

There are other wrapping situations in which `numpy.i` may be helpful when you encounter them.

- In some situations, it is possible that you could use the `%numpy_typemaps` macro to implement typemaps for your own types. See the *Other Common Types: bool* or *Other Common Types: complex* sections for examples. Another situation is if your dimensions are of a type other than `int` (say `long` for example):

```
%numpy_typemaps(double, NPY_DOUBLE, long)
```

- You can use the code in `numpy.i` to write your own typemaps. For example, if you had a five-dimensional array as a function argument, you could cut-and-paste the appropriate four-dimensional typemaps into your interface file.

The modifications for the fourth dimension would be trivial.

- Sometimes, the best approach is to use the `%extend` directive to define new methods for your classes (or overload existing ones) that take a `PyObject*` (that either is or can be converted to a `PyArrayObject*`) instead of a pointer to a buffer. In this case, the helper routines in `numpy.i` can be very useful.
- Writing typemaps can be a bit nonintuitive. If you have specific questions about writing [SWIG](#) typemaps for NumPy, the developers of `numpy.i` do monitor the [Numpy-discussion](#) and [Swig-user](#) mail lists.

A Final Note

When you use the `%apply` directive, as is usually necessary to use `numpy.i`, it will remain in effect until you tell [SWIG](#) that it shouldn't be. If the arguments to the functions or methods that you are wrapping have common names, such as `length` or `vector`, these typemaps may get applied in situations you do not expect or want. Therefore, it is always a good idea to add a `%clear` directive after you are done with a specific typemap:

```
%apply (double* IN_ARRAY1, int DIM1) {(double* vector, int length)}
#include "my_header.h"
%clear (double* vector, int length);
```

In general, you should target these typemap signatures specifically where you want them, and then clear them after you are done.

Summary

Out of the box, `numpy.i` provides typemaps that support conversion between NumPy arrays and C arrays:

- That can be one of 12 different scalar types: signed char, unsigned char, short, unsigned short, int, unsigned int, long, unsigned long, long long, unsigned long long, float and double.
- That support 74 different argument signatures for each data type, including:
 - One-dimensional, two-dimensional, three-dimensional and four-dimensional arrays.
 - Input-only, in-place, argout, argoutview, and memory managed argoutview behavior.
 - Hard-coded dimensions, data-buffer-then-dimensions specification, and dimensions-then-data-buffer specification.
 - Both C-ordering (“last dimension fastest”) or Fortran-ordering (“first dimension fastest”) support for 2D, 3D and 4D arrays.

The `numpy.i` interface file also provides additional tools for wrapper developers, including:

- A [SWIG](#) macro (`%numpy_typemaps`) with three arguments for implementing the 74 argument signatures for the user's choice of (1) C data type, (2) NumPy data type (assuming they match), and (3) dimension type.
- Fourteen C macros and fifteen C functions that can be used to write specialized typemaps, extensions, or inlined functions that handle cases not covered by the provided typemaps. Note that the macros and functions are coded specifically to work with the NumPy C/API regardless of NumPy version number, both before and after the deprecation of some aspects of the API after version 1.6.

3.7.1 Testing the numpy.i typemaps

Introduction

Writing tests for the `numpy.i` SWIG interface file is a combinatorial headache. At present, 12 different data types are supported, each with 74 different argument signatures, for a total of 888 typemaps supported “out of the box”. Each of these typemaps, in turn, might require several unit tests in order to verify expected behavior for both proper and improper inputs. Currently, this results in more than 1,000 individual unit tests executed when `make test` is run in the `numpy/tools/swig` subdirectory.

To facilitate this many similar unit tests, some high-level programming techniques are employed, including C and SWIG macros, as well as Python inheritance. The purpose of this document is to describe the testing infrastructure employed to verify that the `numpy.i` typemaps are working as expected.

Testing organization

There are three independent testing frameworks supported, for one-, two-, and three-dimensional arrays respectively. For one-dimensional arrays, there are two C++ files, a header and a source, named:

```
Vector.h
Vector.cxx
```

that contain prototypes and code for a variety of functions that have one-dimensional arrays as function arguments. The file:

```
Vector.i
```

is a SWIG interface file that defines a python module `Vector` that wraps the functions in `Vector.h` while utilizing the typemaps in `numpy.i` to correctly handle the C arrays.

The Makefile calls `swig` to generate `Vector.py` and `Vector_wrap.cxx`, and also executes the `setup.py` script that compiles `Vector_wrap.cxx` and links together the extension module `_Vector.so` or `_Vector.dylib`, depending on the platform. This extension module and the proxy file `Vector.py` are both placed in a subdirectory under the `build` directory.

The actual testing takes place with a Python script named:

```
testVector.py
```

that uses the standard Python library module `unittest`, which performs several tests of each function defined in `Vector.h` for each data type supported.

Two-dimensional arrays are tested in exactly the same manner. The above description applies, but with `Matrix` substituted for `Vector`. For three-dimensional tests, substitute `Tensor` for `Vector`. For four-dimensional tests, substitute `SuperTensor` for `Vector`. For flat in-place array tests, substitute `Flat` for `Vector`. For the descriptions that follow, we will reference the `Vector` tests, but the same information applies to `Matrix`, `Tensor` and `SuperTensor` tests.

The command `make test` will ensure that all of the test software is built and then run all three test scripts.

Testing header files

`Vector.h` is a C++ header file that defines a C macro called `TEST_FUNC_PROTOS` that takes two arguments: `TYPE`, which is a data type name such as `unsigned int`; and `SNAME`, which is a short name for the same data type with no spaces, e.g. `uint`. This macro defines several function prototypes that have the prefix `SNAME` and have at least one argument that is an array of type `TYPE`. Those functions that have return arguments return a `TYPE` value.

`TEST_FUNC_PROTOS` is then implemented for all of the data types supported by `numpy.i`:

- `signed char`
- `unsigned char`
- `short`
- `unsigned short`
- `int`
- `unsigned int`
- `long`
- `unsigned long`
- `long long`
- `unsigned long long`
- `float`
- `double`

Testing source files

`Vector.cxx` is a C++ source file that implements compilable code for each of the function prototypes specified in `Vector.h`. It defines a C macro `TEST_FUNCS` that has the same arguments and works in the same way as `TEST_FUNC_PROTOS` does in `Vector.h`. `TEST_FUNCS` is implemented for each of the 12 data types as above.

Testing SWIG interface files

`Vector.i` is a [SWIG](#) interface file that defines python module `Vector`. It follows the conventions for using `numpy.i` as described in this chapter. It defines a [SWIG](#) macro `%apply_numpy_typemaps` that has a single argument `TYPE`. It uses the [SWIG](#) directive `%apply` to apply the provided typemaps to the argument signatures found in `Vector.h`. This macro is then implemented for all of the data types supported by `numpy.i`. It then does a `%include "Vector.h"` to wrap all of the function prototypes in `Vector.h` using the typemaps in `numpy.i`.

Testing Python scripts

After `make` is used to build the testing extension modules, `testVector.py` can be run to execute the tests. As with other scripts that use `unittest` to facilitate unit testing, `testVector.py` defines a class that inherits from `unittest.TestCase`:

```
class VectorTestCase(unittest.TestCase):
```

However, this class is not run directly. Rather, it serves as a base class to several other python classes, each one specific to a particular data type. The `VectorTestCase` class stores two strings for typing information:

self.typeStr

A string that matches one of the SNAME prefixes used in `Vector.h` and `Vector.cxx`. For example, "double".

self.typeCode

A short (typically single-character) string that represents a data type in numpy and corresponds to `self.typeStr`. For example, if `self.typeStr` is "double", then `self.typeCode` should be "d".

Each test defined by the `VectorTestCase` class extracts the python function it is trying to test by accessing the `Vector` module's dictionary:

```
length = Vector.__dict__[self.typeStr + "Length"]
```

In the case of double precision tests, this will return the python function `Vector.doubleLength`.

We then define a new test case class for each supported data type with a short definition such as:

```
class doubleTestCase(VectorTestCase):
    def __init__(self, methodName="runTest"):
        VectorTestCase.__init__(self, methodName)
        self.typeStr = "double"
        self.typeCode = "d"
```

Each of these 12 classes is collected into a `unittest.TestSuite`, which is then executed. Errors and failures are summed together and returned as the exit argument. Any non-zero result indicates that at least one test did not pass.

ACKNOWLEDGEMENTS

Large parts of this manual originate from Travis E. Oliphant's book [Guide to NumPy](#) (which generously entered Public Domain in August 2008). The reference documentation for many of the functions are written by numerous contributors and developers of NumPy.
